Preface	xi
List of Contributors	xiii

## Section 1: Functional Anatomy of the Serotonergic System

1.1 Evolution of Serotonin: Sunlight to Suicide	
Efrain C. Azmitia . . . . .	3
1.2 Genetic Organization of the Serotonergic System	
Ursula M. D'Souza and Ian W. Craig . . . . .	23
1.3 The Neuroanatomy of the Serotonergic System	
Jean-Pierre Hornung . . . . .	51
1.4 Ultrastructure of the Serotonin Innervation in the Mammalian Central Nervous System	
Laurent Descarries, Mustapha Riad and Martin Parent . . . . .	65
1.5 Classification and Signaling Characteristics of 5-HT Receptors	
Joël Bockaert, Sylvie Claeysen, Aline Dumuis and Philippe Marin . . . . .	103
1.6 Distribution of 5-HT Receptors in the Central Nervous System	
Guadalupe Mengod, Roser Cortés, M. Teresa Vilaró and Daniel Hoyer . . . . .	123
1.7 Measuring Serotonin Activity <i>in vivo</i> in the Brains of Animals and Humans	
Charles A. Marsden . . . . .	139

## Section 2: The Neurophysiology of Serotonin

2.1 Activity of Brain Serotonergic Neurons in Relation to Physiology and Behavior	
Barry L. Jacobs and Casimir A. Fornal . . . . .	153
2.2 Electrophysiology of Serotonin Receptors	
Gerard J. Marek . . . . .	163
2.3 Tryptophan Hydroxylase and Serotonin Synthesis Regulation	
Hiroyuki Hasegawa and Kazuhiro Nakamura . . . . .	183
2.4 The Degradation of Serotonin: Role of MAO	
Marco Bortolato, Kevin Chen and Jean C. Shih . . . . .	203
2.5 Cellular Effects of Serotonin in the CNS	
Rodrigo Andrade and Sheryl G. Beck . . . . .	219
2.6 Serotonergic Feedback Control	
Trevor Sharp . . . . .	233
2.7 Tryptophan Depletion and Serotonin Release – A Critical Reappraisal	
Matthijs G.P. Feenstra and Geoffrey van der Plasse . . . . .	249

2.8	Serotonin Interaction with Other Transmitter Systems Albert Adell, Analía Bortolozzi, Llorenç Díaz-Mataix, Noemí Santana, Pau Celada and Francesc Artigas . . . . .	259
2.9	Serotonergic Regulation of Rhythmical Activity of the Brain, Concentrating on the Hippocampus Robert P. Vertes . . . . .	277
2.10	5-HT Neurons and Central CO <sub>2</sub> Chemoreception Carolín I. Dohle and George B. Richerson . . . . .	293

### Section 3: Serotonin and Behavioral Control

3.1	Serotonin and Development Patricia M. Whitaker-Azmitia . . . . .	309
3.2	Serotonin and Basal Sensory–Motor Control Robert J. Carey. . . . .	325
3.3	Role of the Serotonergic System in Appetite and Ingestion Control Michelle D. Lee and Peter G. Clifton . . . . .	331
3.4	Serotonin and Sexual Behavior Lynda Uphouse and Jutatip Guptarak . . . . .	347
3.5	Serotonin in Mood and Emotion Julie G. Hensler . . . . .	367
3.6	Serotonin and the Neurobiology of Anxious States Christopher A. Lowry and Matthew W. Hale . . . . .	379
3.7	Role of Serotonin in Brain Reward and Regulation of Alcohol Drinking Behavior W.J. McBride . . . . .	399
3.8	Role of Central Serotonin in Impulsivity and Compulsivity: Comparative Studies in Experimental Animals and Humans Trevor W. Robbins and Molly J. Crockett . . . . .	415
3.9	Experimental Studies on the Role(s) of Serotonin in Learning and Memory Functions Jean-Christophe Cassel . . . . .	429
3.10	Social Behavior and Serotonin Elif Aysimi Duman and Turhan Canli . . . . .	449
3.11	Serotonin in Pain and Pain Control Claudia Sommer . . . . .	457

### Section 4: Serotonin in Disease Conditions

4.1	The Impact of Stress on Serotonergic Neurotransmission Astrid C.E. Linthorst and Johannes M.H.M. Reul. . . . .	475
-----	---	-----

4.2	The Role of Serotonin in Depression Gregory V. Carr and Irwin Lucki . . . . .	493
4.3	The Role of Serotonin in Drug Addiction Christian P. Müller, Martin E. Pum, Gunter Schumann and Joseph P. Huston . . . . .	507
4.4	The Serotonergic System in Obsessive-Compulsive Disorder Addy van Dijk, Andre Klompmakers and Damiaan Denys . . . . .	547
4.5	The Role of Serotonin in Attention-Deficit Hyperactivity Disorder (ADHD) Robert D. Oades . . . . .	565
4.6	Serotonin and Schizophrenia Boris B. Quednow, Mark A. Geyer and Adam L. Halberstadt . . . . .	585
4.7	Serotonin and Serotonin Receptors in Hallucinogen Action Adam L. Halberstadt and David E. Nichols . . . . .	621
4.8	The Role of Serotonin in Cortical Development: Implications for Autism Spectrum Disorder Christine F. Hohmann and Mary E. Blue . . . . .	637
4.9	Serotonin in Panic and Anxiety Disorders Francisco S. Guimarães, Hélio Zangrossi Jr, Cristina M. Del Ben and Frederico G. Graeff . . . . .	667
4.10	Serotonin and Aggression Isabel M. Quadros, Aki Takahashi and Klaus A. Miczek . . . . .	687
4.11	Altered Serotonin Function in Anorexia and Bulimia Nervosa Vikas Duvvuri, Ursula F. Bailer and Walter H. Kaye . . . . .	715
4.12	Genetic, Epigenetic and Environmental Factors in Serotonin-Associated Disease Conditions Eva Friedel and Andreas Heinz . . . . .	731
4.13	The Behavioral Genetics of Serotonin: Relevance to Anxiety and Depression Olivia F. O’Leary, John F. Cryan . . . . .	749
4.14	Functional Pharmacogenetics of Serotonin Receptors in Psychiatric Drug Action Olga O. Yevtushenko and Gavin P. Reynolds . . . . .	791

# Preface

After more than 60 years of intensive research, the serotonin system has lost nothing of its attraction to researchers and people interested in the brain mechanisms of subjective experience and behavior. In fact, the more that becomes known about serotonin, the more it uncovers a brilliant complexity, which raises even more questions. Our understanding of the brain serotonergic system has been largely driven by pharmacological research. This is not surprising, given that the serotonin system, with its many specific genes and a steadily increasing number of proteins, offers a huge variety of possible pharmacological targets. Many of them proved to be effective in treating psychiatric diseases, such as depression and anxiety disorders. By the way, pharmacological progress was also shaping the theories about the origin of the disease and serotonin function in general. The parallel development of a behavioral neuroscience of serotonin always made use of the pharmacological tools. However, it is more focused on a general idea of the role of serotonin in behavior, a master plan, a predominant role, something like a brand identity. Needless to say, a full understanding of the role of a neurotransmitter in disease conditions is inconceivable without having a concept of how the transmitter system works in normal behavior. Despite many previous and still ongoing attempts to reduce serotonin to one key role, it has never been proved to fulfill any narrow claim. What we know for sure is only that there is no behavior and plasticity without it, while too much of it is equally detrimental. Its fate in behavioral neuroscience is still its omnipresent involvement in virtually every behavior, which is best reflected on the physiological level by the fact that a relatively small number of serotonin neurons modulate, by their projections, virtually all other regions of the central nervous system. To date the serotonergic system successfully resists a reductionist approach, but precisely that may finally be its beauty.

For this book we have invited well-known experts in many different fields of serotonin neuroscience to contribute their findings and views. The result is a compilation that presents a broad picture of how serotonin in the brain influences behavior and subjective experiences (including the coordinated role of physiology). The book is divided into four sections. In Section 1, state of the art knowledge of the functional anatomy of the serotonin system is presented. It starts with a view on the evolution of the serotonergic system. The genetic organization of the system is then outlined, where the genes that are unique for serotonergic signaling and their characteristics are discussed. This is followed by chapters that summarize the gross anatomy and ultrastructure of the serotonergic neurons, projections, and synapses in the brain. Serotonin receptors are the essential proteins that ‘translate’ the extracellular serotonin signal into intracellular signals. The distribution of the many different serotonin receptors and their particular signaling characteristics are presented in subsequent chapters. A further chapter reviews the ways in which serotonin activity can be detected in the brains of animals and humans during behavior.

Section 2 provides an overview of the neurophysiology of the serotonin system, which is the basis for an understanding of normal behavioral processes and pathological conditions. The activity of serotonergic neurons is discussed extensively, followed by an overview of the electrophysiology of the serotonin receptors. Essential for serotonin signaling are its synthesis and later inactivation metabolism. Both are discussed in detail, with the focus on the enzymes tryptophan hydroxylase and monoamine oxidase. The behavioral effects of serotonin precursor over- and undersupply are also critically evaluated. Once serotonin is released in the brain, it exerts effects on postsynaptic cells and subsequently other transmitter systems. These effects are reviewed in two chapters. Postsynaptic effects need to be in a certain ‘activation window’ that on the one hand assures appropriate levels of plasticity, and on the other prevents dangerous overactivation. This is achieved by a number of feedback control systems, which are discussed in the next chapter. As has become evident in recent years, serotonin also plays a major role in the generation of rhythmic activity in the brain and in CO<sub>2</sub> chemoreception; these aspects are summarized in separate chapters.

Section 3 deals with the role of serotonin in behavioral control, focusing on normal behavior. It starts with an in-depth review of how serotonin guides brain development, and how disturbances of the serotonergic system during prenatal to adolescent development affect adult behavior. The role of serotonin in a number of behaviors and subjective states is then discussed in detail in separate chapters focusing on motor control, appetite and ingestion, sexual behavior, mood and emotion, anxious states, reward and reinforcement, impulsivity, learning and memory, social behavior, and pain control.

In Section 4 the role of the serotonergic system in pathological conditions is extensively reviewed, discussing psychiatric disorders and serotonin-based pharmacotherapies. As such, separate chapters are devoted to the role of serotonin in stress, depression, drug addiction, hallucinogenic drug action, obsessive compulsive disorders, attention-deficit hyperactivity

disorder, schizophrenia, hallucinogenic drug action, autism, panic and anxiety disorders, aggression, and anorexia and bulimia. Two further chapters focus on how genetic, epigenetic, and environmental factors influence psychiatric disorders by their interaction with the serotonergic system in humans and in animals, respectively. A final chapter discusses the pharmacogenetics of serotonin receptors in psychiatric drug action.

While the contribution of serotonin to many behaviors is evident, the claim that ‘it is involved in everything, but responsible for nothing’ might still hold true. However, we are now at the edge of a system’s role in behavior. Further success can only be achieved with a thorough understanding of single transmitter systems and how they influence others. As such, this book is an attempt to present the current state of knowledge on the serotonin system in the control of behavior. We hope that it may serve as reference and starting point for future systems approaches incorporating the serotonergic system into a larger view of how subjective experience and behavior is organized by the brain.

# Evolution of Serotonin: Sunlight to Suicide

Efrain C. Azmitia\*

*Department of Biology and Psychiatry, Center for Neuroscience, New York University,  
Washington Square East, New York*

**Abstract:** Serotonin is involved in many of the behaviors and biological systems that are central to human life, extending from early developmental events related to neurogenesis and maturation, to apoptosis and neurodegeneration that underlie dementia and death. How can a single chemical be so powerful in determining the quality and quantity of human life? In this chapter, the evolution of serotonin and its biosynthetic pathways from tryptophan are examined. The essential components of the serotonin biosynthetic pathway are highly conserved. Tryptophan-based chemicals, including serotonin, melatonin and auxin, have important action in the differentiation, mitosis and survival of single cell organisms. As the complexity of life evolved into multicellular organisms, especially plants, serotonin levels rose dramatically. The importance of tryptophan, serotonin and auxin is evident in photosynthesis and plant growth. When the animal kingdom began, the ability to synthesize tryptophan was lost, and serotonin levels dropped accordingly. Animals had to develop many special mechanisms to secure tryptophan from their diets, and to carefully conserve its integrity during circulation throughout the body. There was the emergence of multiple receptors and reuptake proteins that permit serotonin actions without utilization of serotonin itself. Serotonin receptors appear as early as the blastula and gastrula stages of embryonic development, and continually monitor and regulate ontogenic changes as it serves phylogenetic evolution.

The most amazing concept to emerge from an analysis of serotonin evolution is its relation to light. Beginning with the light-absorption properties of the indole ring of tryptophan, a direct path can be drawn to the effects of sunlight on photosynthesis and serotonin levels in plants. Progressing further in phylogeny, the effects of sunlight are seen on serotonin levels and on mood, sleep and suicide ideation in humans. The focus on the evolution of serotonin leads from an awareness of the beginning of life to the current human struggle to enjoy our dominant position on earth.

**Keywords:** seasonal affective disorder (SAD), tryptophan, auxin, hallucinogens, 5-HT<sub>1A</sub> receptor, photosynthesis, homeostasis indole, chloroplast, fungus, metazoa.

## Introduction

It has always been an enigma how serotonin, a monoamine neurotransmitter, can have such diverse and important functions in the human brain. The question is further complicated when it is recognized that serotonin exists in all the organs of the body (e.g., the skin, gut, lung, kidney, liver, and testis) and in nearly every living organism on Earth (e.g., fungi, plants, and animals) (Azmitia, 1999). Serotonin is phylogenetically ancient, and evolved prior to the appearance of neurons. Whatever function serotonin has in the brain, it should be consistent with its evolutionary history. However, little attention has been given to the biological emergence of serotonin. Most neuroscience studies focus on serotonin in mediating particular behaviors (e.g., feeding, sex, sleep, and learning) or its

involvement in specific brain disorders (e.g., depression, Alzheimer's disease and autism). A broader view has been rarely raised. Over the past 50 years, several scientists have proposed general organismic roles for brain serotonin (Brodie and Shore, 1957; Woolley, 1961; Scheibel *et al.*, 1975). A more comprehensive theory that includes expanded functions proposes that serotonin acts as a homeostatic regulator which integrates mind and body with the outside world (Azmitia, 2001, 2007). In reading this chapter, it is hoped that the reader will appreciate why serotonin came to be so important in the mental health of humans.

The evolution proposed for serotonin begins with a discussion of its precursor tryptophan and its metabolites in unicellular organisms nearly 3 billion years ago. To make serotonin from tryptophan, oxygen is needed, and in the earliest geological times the Earth's atmosphere had little oxygen. Thus, serotonin is made specifically

\*E-mail: ecal@nyu.edu

**Table 1** Light spectrum of wavelengths that reach the Earth

Type	Wavelength (nm)
Infrared	>1000
Red	700–630
Orange	630–590
Yellow	590–560
Green	560–490
Blue	490–450
Violet	450–400
UVA	400–315
UVB	315–380
UVC	280–100

in unicellular systems capable of photosynthesis and the cellular production of oxygen. The conserved serotonin biosynthetic pathway began in the unicellular systems of cyanobacteria, green algae and fungi, and continually evolved to its current position in the human brain.

Photosynthesis is dependent on the energy derived from sunlight. The amount of light reaching Earth has seasonal variation and, because of the Earth's tilting, is most noticeable at the polar extremes. Light can be roughly divided into ultraviolet (UV) and visible light (Table 1). In humans, UVB radiation produces sunburn and some forms of skin cancer, while UVA (black light) will produce skin discoloration and is necessary for vitamin D production. Glass and plastic can block UVB rays. The two types of light mainly absorbed during photosynthesis in plants are blue light and red light. The light most effective in alleviating the depression associated with seasonal affective disorder is blue light.

## Tryptophan

### Light capturing

#### Indole

Indole is an organic compound consisting of a benzene ring and a pyrrole ring (Figure 1). The origin of the first photosynthetic pathway is proposed to be the photo-oxidation of uroporphyrinogen (a tetrapyrrole) by UVC, and this oxidation is accompanied by the release of molecular hydrogen. The oxidation of uroporphyrinogen to uroporphyrin, the first biogenetic porphyrin, could have occurred anaerobically and abiologically on the primordial Earth 3 billion years ago (Mercer-Smith *et al.*, 1985). The indole structure can be found in many organic compounds, like the amino acid tryptophan, and in tryptophan-containing enzymes and receptors, alkaloids and pigments. The indole ring is electron rich and will lose an

**Figure 1** The indole structure consists of aromatic pyrrole and benzene rings. In the indole ring, the electrons are merged and a large pool of electrons becomes available for redox reactions.

electron (oxidized) to an electrophilic compound, like a heavy metal, to decrease its oxidation number. The most reactive position on the indole structure for electrophilic aromatic substitution is C-3, which is  $10^{13}$  times more reactive than benzene. Presently, cationic porphyrins are known to bind to the tryptophan moiety of proteins (Zhou *et al.*, 2008). A similar situation to tryptophan occurs with chlorophyll, the light-capturing molecule of plants.

#### Photosynthesis

Most proteins are endowed with an intrinsic UV fluorescence because they contain aromatic amino acids, particularly phenylalanine, tyrosine and tryptophan. Comparing the three aromatic amino acids, tryptophan has the highest fluorescence quantum yield, overshadowing markedly the emissions of the other two. Generally, a distinction is made between tryptophan and non-tryptophan fluorescence. The tryptophan amino acid contains an indole backbone and absorbs light. Free tryptophan has characteristic fluorescence absorption at UVB (Borkman and Lerman, 1978; Lin and Sakmar, 1996), and the fluorescence emission is in the range of UVA-blue light (Du *et al.*, 1998). This amino acid in proteins is needed for solar energy to drive photosynthesis in cyanobacteria, algae and plants (Vavilin *et al.*, 1999). Solar energy conversion in photosynthesis involves electron transfer between an excited donor molecule and an acceptor molecule that are contained in the reaction center, an intrinsic membrane protein pigment complex (Wang *et al.*, 2007). In the photosynthetic reaction centers of *Rhodobacter sphaeroides*, there are 39 tryptophan residues. Initiation of the electron

transfer reaction by excitation results in a transient change in the absorbance at UVB, near the peak of the tryptophan absorbance band. According to Wang *et al.* (2007):

Given the similarity of the core features of the photosynthetic complexes from bacteria and plants, it is very likely that this same framework holds true for the initial electron transfer reaction of photosynthesis in general and possibly for other protein-mediated electron transfer reactions on similar time scales.

Absorption of blue light waves in chloroplasts leads to excitation of the indole structure of tryptophan so that it loses one of the electrons from its indole ring structure – it becomes oxidized. The electron that is lost from the indole ring passes through the intermediary of heavy metals to make its way down the electron chain. This process leads to the production of reducing cofactors such as nicotinamide adenine dinucleotide (NADH), or reduction of  $\text{H}_2\text{O}$  to  $\text{O}_2$ . In bacterial ferric cytochrome P-450, the initial event of photoreduction is the photo-ionization of tryptophan in the active site of P-450 (Pierre *et al.*, 1982). A laser flash at 265nm, near the UVB range, triggers the nanosecond event of a protein structural change coincident with an ejection of electrons, and is followed by the photoreduction of the heme moiety (Bazin *et al.*, 1982). The transfer of electrons between tryptophan and the heavy metals occurs at extremely rapid rates of several nanoseconds (Shih *et al.*, 2008). This process takes place during photosynthesis, and is the procedure that converts solar energy into biological energy.  $\text{CO}_2$  and water are converted to  $\text{O}_2$  and glucose. This is the most important biochemical process on Earth. The Earth's atmosphere contains 20 percent oxygen, and drives the biological evolution of aerobic organisms. Photosynthesis occurs in certain bacteria (e.g., cyanobacteria), algae (e.g., green algae) and all plants (Bryant and Frigaard, 2006).

### *Chloroplasts*

Plants evolved a specialized intracellular organelle, the chloroplast, not only to capture light, but also as the source of tryptophan synthesis. This organelle may have evolved from captured cyanobacteria, and contains several hundred copies of chlorophyll. Chlorophyll became the universal transformer of solar energy in bioenergetics, and is sensitive to both blue and red light. In addition to its role in photosynthesis, blue light absorbance has been implicated as an early step in certain blue light-mediated morphogenic events (Rubinstein and Stern, 1991). The spectra for blue light-stimulated stomatal opening and phototropism are specialized for sensory transduction in the chloroplast (Quiñones *et al.*, 1998). Thus blue light in plants not only underlies photosynthesis, it also produces

morphological plasticity in the plant leaf to promote sensory transduction of light energy into bioenergy. Structural and functional advantages of the chlorophyll molecule may have determined its selection in evolution (Mauzerall, 1973). Chloroplast have a high need for tryptophan because of its light-absorption functions.

### *Amino acid*

Tryptophan is the largest and most hydrophobic amino acid, and provides important folding signals to large proteins (Aoyagi *et al.*, 2001). Tryptophan is the least used amino acid in the composition of protein molecules, generally comprising around 1–2 percent of the protein weight. In the basic genetic code, only one code is used for tryptophan, 'UGG', and this is flanked by stop codons on UAA, UAG, and UGA. Yet many important molecules are derived from tryptophan, including the nucleic acids adenosine and thymidine in DNA. Furthermore, a novel nucleolar protein, WDR55, carries a tryptophan–aspartate repeat motif and is involved in the production of ribosomal RNA (rRNA) (Iwanami *et al.*, 2008). These findings suggest that WDR55 is a nuclear modulator of rRNA synthesis, cell cycle progression, and embryonic organogenesis. Thus, despite its limited abundance, tryptophan and its associated molecules are involved in all cellular aspects of the organism's life, and serve key regulatory roles in mitosis (Humphrey and Enoch, 1998), cell movement (Efimenko *et al.*, 2006) and maturation (Cooke *et al.*, 2002).

The synthesis of tryptophan takes several key enzymes: anthranilate synthase (EC 4.1.3.27), anthranilate phosphoribosyl-transferase (EC 2.4.2.18), anthranilate phosphoribosyl-isomerase (EC 5.3.1.24), indole-3-glycerol-phosphate synthase (EC 4.1.1.4) and tryptophan synthase (EC 4.2.1.20) (Figure 2). These enzymes are found in primitive unicellular organisms and in all plant systems. In many organisms there are isoforms of these that provide redundancy in tryptophan synthesis. In plants, tryptophan biosynthetic enzymes are synthesized as higher molecular weight precursors and then imported into chloroplasts and processed into their mature active forms (Zhao and Last, 1995). Chloroplast organelles contain the genes and enzymes, similar to those seen in cyanobacteria, required for tryptophan synthesis. Despite the abundant amount of tryptophan made by lower organisms, animals are tryptophan autotrophs, which lack the genes necessary for tryptophan synthesis. Tryptophan for serotonin synthesis is obtained from food. Often the main source of food is proteins from other animals; despite the fact that the amount of tryptophan in protein from animal sources is the least compared to the other amino acids.

**Figure 2** The five enzymatic steps in the synthesis of tryptophan from chorismate; the names of each are provided in the text. In plants, these enzymes and the chloroplast genes for them are located within the chloroplast. In animals, the genes are inactive and all tryptophan is obtained from external sources.

Tryptophan levels are much higher in fruits, vegetables and nuts. Once digested, tryptophan exists in a free and bound form in the plasma. Only the free form is available for transport into the brain, and its transport must compete with the uptake of all the other, more abundant, aromatic amino acids (e.g., tyrosine, phenylalanine, leucine, isoleucine, valine and methionine) (Curzon *et al.*, 1973). The synthesis of serotonin in humans appears to be restricted to a few cell types (e.g., mast cells and neurons). Selected

cells in all organs have specific uptake proteins for capturing serotonin from the plasma where it is stored. The importance of this will be discussed later.

The capture of light by tryptophan is used at the active site by nearly all proteins (e.g., chlorophyll, rhodopsin and skin pigment cells) which capture light (Angiolillo and Vanderkooi, 1996). A long-range transfer of electrons to cytochromes from tryptophan can be demonstrated with a number of proteins, including paralbumin, aldolase and

liver alcohol dehydrogenase (Dadak *et al.*, 1992). Thus, tryptophan is very sensitive to light in a variety of protein environments, and readily releases its electrons from the excited triplet state upon light exposure. This ability to transfer electrons is not only utilized in the initial events of photosynthesis. In the light receptor rhodopsin, there is rotation of a single tryptophan molecule when meta I is converted to meta II after illumination (Chabre and Breton, 1979). Photoactivation of rhodopsin involves a change in the relative disposition of transmembrane helices 3 and 6, which contain Trp126 and Trp265 respectively, within the receptor (Lin and Sakmar, 1996). These studies show that tryptophan serves key photo-signaling properties in light receptor rhodopsin, probably the most primitive of all G-protein receptors.

Tryptophan's ability to absorb UV light can be put to advantage. The bacterium *Bacillus subtilis* is protected from the lethal actions of ultraviolet radiation by tryptophan (Hunt, 1964). UV and X-ray light produce luminescence of tryptophan (Steen, 1967). This absorption provides protection by filtering harmful UV light before it can reach the underlying DNA and photoreceptors. The UV absorbance in chicken eye aqueous is partially accounted for by the presence of tryptophan (Ringvold *et al.*, 2000).

Tryptophan has many functions in the cells, not only as an essential amino acid and chromophore but also because it makes niacin and all its precursors. NAD<sup>+</sup> and NADP<sup>+</sup> cofactors are involved in nearly all aspects of cell metabolism (Cox *et al.*, 2000). *De novo* synthesis of nicotinamide adenine dinucleotides from tryptophan is a more important source of these coenzymes than is the utilization of dietary nicotinamide or nicotinic acid (Bender and Olufunwa, 1988). In the nucleus, niacin is important for DNA repair, and tryptophan capture of light appears to be responsible for the DNA photo-damage associated with mutation and cell death in the absence of repair (Friedberg *et al.*, 1995).

### ***Tryptophan derivatives***

Photosynthesis is a major risk to cells as well as nutritional benefits. Photosynthesis can be perturbed by upsetting the balance between the rates of light collection and light use, resulting in the production of reactive oxygen species (ROS) (Asada, 1996). Left unchecked, ROS are damaging to protein function and membrane integrity, and pose a serious threat to photosynthetic organisms. UV light reaction with tryptophan generates many photoproducts having deleterious actions. UVB radiation of N-formylkynurenine generates free radicals such as singlet oxygen and superoxide (Grossweiner, 1984). Tryptophan

also generates fluorescent photoproducts which inhibit the growth and differentiation of cultured fertilized sea urchin eggs and mouse fibroblasts (Zigman and Hare, 1976). Thus a wide range of cells, from bacteria to mammals, are harmed by photo-oxidized tryptophan. The damage done to the human skin by sunlight can be largely attributed to the actions of tryptophan metabolism via the pyrrolase, kynurenine and niacin pathways (Binazzi and Calandra, 1975). Ultraviolet light sensitizes tryptophan to enhance the photooxidation of tyrosine to dopachrome, a precursor of melanin (Badu and Joshi, 1992).

The critical problem in oxygen generating cells was what to do with all the reactive oxidizing chemicals produced during the generation of oxygen. Many of the derivatives of tryptophan evolved to function as antioxidant molecules in simple cells long before they assumed more complex functions in animals and humans. Substituted indoles are derivatives of the tryptophan-based tryptamine alkaloids, such as serotonin, melatonin and auxin; the hallucinogens psilocybin, DMT, 5-MeO-DMT; and the ergots, such as ergotamine and LSD (Schultes and Hofmann, 1973). N-formylkynurenine, 5-methoxytryptamine, auxin and melatonin in prokaryotes function as photosensors, antioxidants and pattern generators for flagella movement, and in defense mechanisms. The defense mechanism may involve attack of plants by fungi, and a role for the phytohormone indole-3-acetic acid or a structurally related compound. Many of these products also have morphogenic actions and play a role in both apoptosis and mitosis. Many of the alkaloids produced from tryptophan have powerful actions on the human brain by acting mainly through the serotonin receptors. The structures of some of these compounds are shown in Figure 3.

Melatonin is a powerful antioxidant (Hardeland, 2005). Melatonin is found in all plants and animals, including algae. Melatonin has been shown to inhibit microtubule function in flagella and in mitosis. Melatonin synthesis has a diurnal rhythm in many protists and plants. It functions as an antioxidant in plants. Seasonal animals use melatonin as a biological signal for the organization of day-length dependent (photoperiodic) annual functions such as reproduction, behavior, coat growth and camouflage coloring (Chaturvedi, 1984). Melatonin is also related to the mechanism by which some amphibians and reptiles change the color of their skin, and, indeed, it was in this connection that the substance was first discovered (Sugden *et al.*, 2004).

Auxin (hydroxyindole acetic acid) is a protective, antioxidant compound found in unicellular organisms (Cooke *et al.*, 2002). Auxin is an important phototropic hormone in plants, is present in bacteria, and functions to stimulate growth and survival. It has many different effects, such as inducing cell elongation and cell division, with

**Figure 3** Many of the alkaloid compounds derived from the tryptophan. Some of these compounds, such as auxin, DMT and melatonin, appear to have been made in protista, occurring before plants. Some of these compounds are known to be potent hallucinogens when ingested by humans (see text). It is reported that serotonin is found in the Fungi Kingdom in yeast cells.

all the subsequent results for plant growth and development (Stern *et al.*, 2002; Mauseth, 2008). Auxin has been reported in several bacteria, and the key enzyme in the auxin synthetic pathway was found in the genome sequence database of *Paenibacillus polymyxa* (Phi *et al.*, 2008). On the cellular level, auxin is essential for cell growth, affecting both cell division and cellular expansion (Perrot-Rechenmann *et al.*, 2002). Depending on the specific tissue, auxin may promote axial elongation (as in shoots), lateral expansion (as in root swelling) or isodiametric expansion (as in fruit growth). Growth and division of plant cells together result in growth of tissue, and specific tissue growth contributes to the development of plant organs. Growth of cells contributes to the plant's size, but uneven localized growth produces bending, turning and orientation of organs – for example, stems turning toward light sources (phototropism), roots growing in response to gravity (gravitropism), and other tropisms. Auxin controls the orientation of cortical microtubules in

maize, perhaps caused by a reduced microtubule turnover (Wiesler *et al.*, 2002). Actin transport is essential for its uneven distribution in plants. Auxin transport inhibitors impair vesicle motility and actin cytoskeleton dynamics in yeast, plants and animals (Dhonukshe *et al.*, 2008). In plants, auxin is synthesized in specialized cells and is transported throughout the plant to influence leaf and root growth. Its specific function in leaves is to move the entire photo-generating organ towards the source of solar energy.

N-formylkynurenine functions as a photosensitizer, and is made in mitochondria by the oxidation of tryptophan (Møller and Kristensen, 2006). 5-Methoxytryptamine is also found in nearly all living organism, and is a key intermediate in the pineal synthesis of melatonin in vertebrates. The production of all other 5-methoxyindoles in the pineal gland as well as in the retina is always larger than that of melatonin. In the pineal gland, 5-methoxytryptophan, for example, is synthesized in a quantity which is 60 to 170

**Figure 4** The synthesis of serotonin from tryptophan. The actions of tryptophan hydroxylase and the general L-amino acid decarboxylase are shown along with the necessary cofactors. The metabolism of serotonin to 5-OH-indole aldehyde is similar to auxin (indole aldehyde), a generated hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). Serotonin is also a precursor for melatonin synthesis in vertebrates.

times greater than that of melatonin, while in the retina the synthesized amount of 5-methoxytryptophan is even 60 to 1000 times greater than that of melatonin (Pévet *et al.*, 1981). This would provide a pathway for the synthesis of melatonin independent of one using 5-hydroxytryptamine, or serotonin.

Below is a list of some of the natural psychoactive drugs synthesized from tryptophan. All these compounds can function as antioxidants in single-cell organisms, and many have been used by man as entactogens and ethoogens for thousands of years.

1. Psilocybin mushrooms (also called psilocybian mushrooms): these are fungi. Kingdom Fungi includes yeasts, rusts, smuts, molds, mushrooms and mildews. Though formerly classified as plants, fungi lack chlorophyll and the organized plant structures of stems, roots and leaves.
2. Dimethyltryptamine (DMT): this occurs in many species of plants, and is commonly used as an hallucinogen via drinking or smoking.
3. Bufotenine: this molecule is found in mushrooms, plants, and the skin and venom of toads (*Bufo* genus).
4. 5-MeO-DMT: this molecule is widely distributed in plants and toads.
5. Ergot, ergotamine: the parent compound of the major hallucinogen LSD has long been known to be produced by a fungus, genus *Claviceps*. The hallucinogen was synthesized by the addition of diethylamide to ergotamine by the chemist Albert Hofmann at the Sandoz Laboratory. LSD is believed to be one of the most potent mind-altering compounds discovered to date.

6. Ibogaine: this is found in a number of plants, principally in a member of the dogbane family known as iboga (*Tabernanthe iboga*).

7. Yohimbine: this is the principal alkaloid of the bark of the West-African evergreen *Pausinystalia yohimbe* Pierre. In Africa, yohimbine has traditionally been used as an aphrodisiac.

## Serotonin

### Biosynthesis

Serotonin is synthesized from tryptophan by two enzymes: tryptophan hydroxylase, which requires molecular oxygen; and tetrahydro-biopterin and aromatic amino-acid decarboxylase, which requires pyridoxal phosphate (Figure 4). It is principally metabolized by monoamine oxidase (A & B) to generate H<sub>2</sub>O<sub>2</sub> and 5-hydroxyindole acetic acid. MAO A & B have been detected in Fungi (Sablin *et al.*, 1998). In the pineal gland of vertebrates, serotonin is methylated to produce melatonin. Precursors of these four enzymes (hydroxylase, decarboxylase, oxidase and methylase) are found in four major kingdoms of life (Bacteria, Fungi, Planta, and Animal).

### Primitive hydroxylase enzymes

One of the solutions for removing excess O<sub>2</sub>, and the potent threat of excess oxidation in cells, is to use the biological machinery that evolved to deal with CO<sub>2</sub>. Anaerobic cells had developed a variety of enzymes for converting CO<sub>2</sub> into biological energy in the form of

glucose, with  $O_2$  as a byproduct. The most common process was to produce the sugar, glyceraldehyde-3 phosphate, a three-carbon sugar produced by three molecules of  $CO_2$ . The first enzymatic step in this reaction involves the attachment of a molecule of  $CO_2$  to the five-carbon sugar, ribulose biphosphate (RuBP). This step is emphasized because the enzyme that catalyzes this initial reaction, and possibly the most abundant enzyme on Earth, is RuBP carboxylase, also known as rubisco. In the very early stages of life on Earth, the carboxylase primarily attached to  $CO_2$ ; however, as  $O_2$  levels increased it was shown that this compound could react more favorably with oxygen (Smith, 1976). The oxygen-based reaction is energy inefficient, but serves to remove excess oxygen during periods of high light flux. This may have been the first enzyme to attach oxygen to a substrate (such as tryptophan to produce 5-hydroxytryptophan (5-HTP)). This enzyme is called a hydroxylase because only a single oxygen is used and the other forms water. RuBP carboxylase has the same phosphate-binding site sequence found in tryptophan biosynthetic enzymes (Wilmanns *et al.*, 1991).

Phenylalanine biosynthesis evolved prior to the addition of branches leading to tyrosine and tryptophan. An evolutionary scenario has been developed that begins with non-enzymatic reactions which may have operated in primitive systems, followed by the evolution of an enzymatic system that pre-dated the divergence of major lineages of modern bacteria (Gram-positive bacteria, Gram-negative purple bacteria, and cyanobacteria) (Ahmad and Jensen, 1998). The bacteria (*Chromobacterium violaceum*) enzyme phenylalanine hydroxylase contains copper ion, and if the enzyme is oxidized it is inactive (electron acceptor, gives up a hydrogen molecule); a single hydrogen ion ( $H^+$ ) is sufficient to reduce the enzyme to a catalytically active state (Pember *et al.*, 1986).  $H_4$ -biopterin reductively activates the enzyme (donates electron). Bacteria (*Pseudomonas fluorescens*) contain a primitive biopterin hydroxylase, cyanide oxygenase, which can convert KCN to  $CO_2$  (Kunz *et al.*, 2001). Many of these enzymatic properties and the use of biopterin cofactor are shared by the mammalian tryptophan hydroxylase, which is the rate-limiting step for serotonin biosynthesis.

The substrates for the primitive hydroxylase enzyme were tryptophan, tyrosine and phenylalanine, all of which can capture light (Grenett *et al.*, 1987; Boularand *et al.*, 1998; Wiens *et al.*, 1998). The hydroxylase enzyme gave rise to a very large number of complex alkaloids in plants, all of which are potent antioxidants in their own right. As we now know, cellular oxidation is important for cell maturation and division, but excess oxidation results in cell death. The synthesis of pharmaceutically important indoles involves the hydroxylase as well as decarboxylase enzymes (Facchini *et al.*, 2000). 5-HTP, the immediate

precursor of serotonin, is formed from tryptophan hydroxylase. This molecule is rapidly converted to serotonin by the ubiquitous carboxylase working in reverse to function as a decarboxylase. Thus, serotonin is produced from tryptophan by enzymes commonly used in anaerobic organisms before  $O_2$  was formed inside cells. Besides the algae, fungi and molds, the most efficient generators of  $O_2$  and serotonin are plants.

### Decarboxylase

The second enzyme in serotonin biosynthesis is tryptophan decarboxylase. The bacteria, *Enterobacteria cloacae* strains that are normally associated with plant roots, produce auxin by using the enzyme indolepyruvate decarboxylase (Zimmer *et al.*, 1994). Aromatic L-amino acid decarboxylase occurs in plants (Facchini *et al.*, 2000). For example, tryptophan decarboxylase in plants leads to the biosynthesis of pharmaceutically active indole alkaloids. These compounds are abundant throughout the plant kingdom, and are known to produce strong psychic or hallucinogenic responses in humans (see Figure 3). In animals, this enzymes losses its specificity for tryptophan and becomes a general aromatic acid decarboxylase. It is likely that as animal cells had a marked reduction in tryptophan due to loss of tryptophan synthesizing enzymes, there was less evolutionary need for a specific tryptophan decarboxylase enzyme.

### Cofactors

Tryptophan is necessary for the synthesis of a variety of cofactors, including biopterin, NADH and pyridoxal phosphate (Nelson and Cox, 2008). Biopterin is an essential cofactor in hydroxylase enzymes, and is necessary for the synthesis of serotonin. NADH and NADPH are involved in nearly every redox reaction in all living cells. They act as both oxidizing and reducing agents. Pyridoxal-5'-phosphate is a catalysis (redox) partner in a variety of reactions involving amino acids (Alexander *et al.*, 1994). Pyridoxal phosphate, the decarboxylase cofactor, in the form of an adduct absorbing at 330–340nm, is suggested as a candidate for photoactivation of the 5-hydroxytryptophan decarboxylation for the role of the photoactive chromophore of decarboxylase. The cofactor pyridoxal-5-phosphate appears to have emerged very early in biological evolution; conceivably, organic cofactors and metal ions were the first biological catalysts (Mehta and Christen, 2005).

### Presence of serotonin

In prokaryotes and algae living under anaerobic or aerobic conditions, the evidence for the presence of serotonin

is weak, although all serotonin biosynthetic enzymes and cofactors are present. The enzymes aromatic amino acid (tryptophan) hydroxylase, tryptophan (aromatic amino-acid) decarboxylase, monoamine oxidase and aromatic hydroxylase are conserved in unicellular organisms. The compounds produced by these enzymes all have roles in light-induced reactions involved in regulating the oxidative reactions in cells. In nearly every unicellular organism, tryptophan and its metabolites (auxin, melatonin and 5-methoxytryptamine) function as light sensors (needed for diurnal rhythms) and as antioxidants. Melatonin and 5-methoxytryptamine appear to be ubiquitous substances found in nearly every living cell (Hardeland, 1999). Auxin is also found in many unicellular organisms (Overbeek, 1940; Jacobs *et al.*, 1985). In fungi, *Candida guilliermondii*, serotonin (and other hydroxylated tryptamines) and ergot derivatives provide protection from UV toxicity and stimulate cell proliferation (Strakhovskaia *et al.*, 1983; Belenikina *et al.*, 1991). *Candida* cannot make oxygen, but depends on oxygen for energy production (obligate aerobes).

### The Plant Kingdom

In plants, the synthesis of serotonin is much higher than in mammals (Garattini and Valzelli, 1965; Smith, 1971; Sparks and Slevin, 1985). The explanation for the high levels of serotonin is abundance of intracellular oxygen, tryptophan, and the enzymes and cofactors necessary for the production of 5-hydroxytryptophan. The levels of serotonin inside plants far exceed those seen in the animal brain, by approximately 100-fold – for example, banana skin has a level of 40 mg/g, while rat hippocampus has a level of 0.4 mg/g. Interestingly, the immediate precursor of 5-HT, 5-HTP, accounts for 20 percent of the total fresh weight in seeds from *Grivonia simplicifolia*, a tropical shrub of west Africa, which has potent medicinal properties (Lemaire and Adosraku, 2002). This seed has 500 times the serotonin levels measured in mammalian brains, where 5-HTP levels are almost undetectable.

The hydroxylase enzyme is of double significance in plants, since not only is molecular oxygen removed from the cell but also a very reactive antioxidant molecule is produced. Serotonin also provides a source for auxin and other important alkaloid production in plants. Despite the high levels of serotonin in plants, most general botany textbooks say nothing on this topic.

### The Animal Kingdom (Table 2)

Animal cells lack chloroplasts, which are organelles central to plant photosynthesis and tryptophan synthesis (Table 2). This lack of a key evolutionary mechanism of life led animals to develop a number of traits in order to

**Table 2** The Metazoa (Animal Kingdom), a major subdivision of life that includes all animals<sup>1</sup>

Phylum	Age (Mya) <sup>2</sup>	Class, genus, species, common names

<sup>1</sup>Fossil records indicate that most metazoan phyla developed during the Cambrian explosion (542–488 million years ago). Many of the classes of vertebrates have fossil records indicating their appearance after this time.

<sup>2</sup>Mya, million years ago.

survive. Animals acquire photosynthesis-produced carbon by forming symbioses with algae and cyanobacteria. These associations are widespread in the phyla Porifera (e.g., sponges) and Cnidaria (e.g., corals, hydra), but are otherwise uncommon or absent from animal phyla (Venn *et al.*, 2008). The sponges (Porifera), the most primitive animal form, evolved about 600 million years ago (Valentine, 2004). Animals had to move to capture organisms that contained tryptophan, and to breathe to extract O<sub>2</sub> from the atmosphere. 5-HT- and 5-hydroxytryptamine-derived alkaloids are found in sponges (Salmoun *et al.*, 2002). This species does not have a nervous system, and feeds by filtration. In hydra, the most primitive animal with a specialized nervous and motor system, 5-HT appears to be localized to sensory cells scattered along the epithelium of the organism. When a distinct nervous system is seen, such as in the flatworm (*Stenostomum leucops*), serotonin neurons are localized there (Wikgren and Reuter, 1985). Serotonin in animals is produced in very low quantities because of the scarcity of tryptophan, and this may explain the few cells that contain 5-HT. As seen in hydra, these specialized 5-HT cells are nevertheless ideally localized, and have pronounced actions on the life of the organism (Figure 5).

**Figure 5** Proposed 5-HT action in hydra nervous system (modified from McCauley, 1997). The 5-HT content is produced and released from a sensory cell and interacts with specific receptors located on neighboring cells. A. An outline of the body plan of hydra shows a very primitive plan, with ectodermal cells lining the outside of the organism. B. A close-up view of the ectodermal layer shows occasional sensory neurons (5-HT?) scattered among non-sensory cells. C. Schematic diagram proposed by McCauley to demonstrate 5-HT release and interaction with a neighboring receptor that activates protein kinase C (PKC).

As these organisms have evolved a neuronal center for responding to their complex environment, serotonin continues to position itself to interact maximally with organizing centers. In aplysia there is a primitive brain, and from the very beginning serotonin is present. According to Marois and Carew (1997):

The results indicate that the first serotonergic cells emerge at mid-embryogenesis and that a total of five cells make up the entire serotonergic system by hatching. The primitive serotonergic cells in aplysia are part of a newly discovered ganglion in aplysia, called the apical ganglion.

The 5-HT neuronal distribution is described in adult aplysia, and the vast serotonergic neuronal distribution through the nervous system, gut and periphery is notable (Goldstein *et al.*, 1984):

Many neuronal cell bodies are stained in addition to the giant cerebral neuron of the cerebral ganglion and cells in the RB cluster of the abdominal ganglia which previously had been characterized biochemically and pharmacologically as being serotonergic. Neuronal cell bodies, both in central ganglia and in the wall of the gut, are encircled by plexuses of serotonergic varicosities. The neuropil of ganglia and the eye also contain fine, immunoreactive axons bearing varicosities. Intraganglionic connectives and nerves contain many stout fluorescent axons. Serotonergic varicosities are also observed in the connective tissue sheath surrounding central ganglia and nerves, as well as in heart and body muscle, blood vessels and gut.

The extensive distribution of serotonergic neurons in lower animals besides the brain and gut is not seen in mammals. The serotonergic neurons are located in the midbrain reticular formation, and have extensive axonal branching throughout the neuroaxis (Azmitia and Segal,

1978; Azmitia and Gannon, 1983) and the gut enterochromaffin cells and myenteric plexus (Gershon and Tack, 2007). Serotonergic axons from the myenteric plexus can innervate the nearby pancreas (Kirchgessner and Gershon, 1990). Mast cells located throughout the body and lying near blood vessels are the principal source of tryptophan hydroxylase in most peripheral tissues. These neuroendocrine mast cells contain serotonin at early gestational stages, and are positioned to serve a trophic function throughout the body as described for auxin in plants (Cutz, 1982).

In the brain of animals, the serotonin system has undergone considerable modification to keep abreast of the increased size and complexity of the brain (Figure 6). The neurons in the brains which contain serotonin actually decrease in relative size as one ascends from aplysia to primates. In lower organisms single serotonin neurons can regulate particular circuits, while in rodents the serotonergic neurons appear to act as large clusters of neurons acting together to influence general brain circuits. Finally, in primates the distribution of neurons in the raphe mid-brain becomes more clustered, and these smaller groups send axons, often myelinated, to specific regions of cortex. This final arrangement allows serotonin to participate in multiple, discrete cortical functions than are not possible in lower mammals. The morphological organization appears to be continually evolving, and may enable more precise distribution of serotonin within the brain of humans.

### Receptors

Capturing light is one of the most primitive functions of a receptor. Primitive rhodopsin GTP-linked receptors, which

**Figure 6** The progression of 5-HT neurons from aplysia to humans. In the aplysia nervous system there are only a few neurons which contain serotonin, and these neurons are large, with extensive connections. In the rodent brain, the 5-HT neurons are arranged in large grouping along the midline of the mesencephalon. The axons from these neurons ascend towards the forebrain in large bundles using mainly the ancient medial forebrain bundle. In primates, the distribution of serotonergic neurons in the mesencephalon is into smaller clusters of neurons. In addition, many of the axons from these neurons are now myelinated. This new arrangement facilitated more precise and rapid delivery of serotonin to forebrain targets (Azmitia, 1987).

function in the human eye in rod cells used for night vision, are present in cyanobacteria (Ruiz-González and Marín, 2004). Cyanobacteria diverged about 2.5 billion years ago. The active site for solar capture in this receptor protein is tryptophan (Chabre and Breton, 1979; Hoersch *et al.*, 2008). The rhodopsin receptor and the 5-HT<sub>1A</sub> receptor show substantial homology (Nowak *et al.*, 2006). In plants (*Arabidopsis thaliana*), a gene sequence was identified with a region of a putative receptor that is similar to sequences of serotonin receptors and other receptors of the so-called rhodopsin receptor family using a G-protein linked mechanism (Josefsson and Rask, 1997). From the gene diversity for serotonin receptors, the 5-HT<sub>1A</sub> receptor is estimated to have evolved 750 million to 1 billion years ago, before the muscarinic, dopaminergic and adrenergic receptor systems (Peroutka and Howell, 1994). This age estimate would indicate that the receptor existed before the evolution of the most primitive animal form, sponges (Porifera), which evolved some 600 million

years ago. If rhodopsin is considered the prototype of the 5-HT<sub>1A</sub> receptor, the emergence of serotonin receptors occurred 3.5 to 2.5 million years ago in cyanobacteria.

Life began in sea water, where Na<sup>+</sup> and Cl<sup>-</sup> ions are highly concentrated. Cells evolved a mechanism to exclude these ions in order to maintain a stable membrane potential, and 'neurotransmitters' evolved the ability to regulate these specific ion channels to rapidly manipulate the membrane potential. Second messengers, e.g., G proteins, c-AMP, and phospholipase C systems, appeared early in evolution and occur in all phyla that have been investigated. With the possible exception of the Porifera and Cnidaria, all the classical 'neurotransmitter' receptor subtypes identified in mammals occur throughout the animal phyla (see Walker *et al.*, 1996). Many of the serotonin receptors are seen in the embryonic stage – for example, H<sup>3</sup>-5-HT binding is seen in the blastula and gastrula of sea urchins (Brown and Shaver, 1989). A gene from the sea urchin encoding the serotonin receptor (5-HT-hpr) was identified and showed sequence homology with the aplysia 5-HT<sub>2</sub> receptor (Katow *et al.*, 2004). Cells expressing the 5-HT receptor appeared near the tip of the archenteron in 33-h post-fertilization larvae. The serotonergic receptor cells developed 7 cellular tracts by 48 hours, and extended short fibers to the larval body surface through the ectoderm. These serotonergic receptor cells are a mesencephalic cell lineage, which appear to transmit serotonin signals to ectodermal cells at the start of gastrulation in sea urchins. In humans, the 5-HT<sub>1A</sub> receptors are at their highest levels before birth (Bar-Peled *et al.*, 1991). In rats, the receptors for serotonin are not only present in the fetus, but can also be modified by injections of agonist (Whitaker-Azmitia *et al.*, 1987). All the invertebrate receptors so far cloned show homologies with mammalian receptors. This indicates that many of the basic serotonin receptor subtypes evolved during early geological periods and appeared at early ontogenic times. As the saying goes, 'Ontogeny recapitulates Phylogeny'.

Tremendous diversity has occurred in receptors in mammals. There are hundreds of serotonin receptor clones, and the human brain has at least 20 separate neuronal transcripts of 5-HT receptors (Moroz *et al.*, 2006). Serotonin is specifically bound to at least 16 specific receptor proteins in the human brain which regulate ion channels, c-AMP levels and kinase activity in neurons. The 5-HT receptors are found in every cell of the body. Why so many, and why such a large distribution? It can be speculated that the difficulty in making and obtaining tryptophan in animals results in low serotonin availability. The function of a receptor is to alert a cell that a chemical is present in the environment, without removing or altering the chemical. Thus, if a chemical is in short supply, the appearance of receptor molecules permits its actions

to be transmitted throughout the organism. In order for this to be maximally effective, an efficient mechanism for the distribution of serotonin is required. Animals have specific tryptophan and serotonin binding proteins in their blood to help transport these molecules to specific target areas, such as the brain. Glial cells at the junction of the blood–brain barrier have special transport proteins for concentrating tryptophan and delivering it to the serotonin neurons (Bachmann, 2002; O’Kane and Hawkins, 2003). Serotonergic neurons developed long, unmyelinated axons that can take up tryptophan and utilize enzymes required for serotonin synthesis throughout the brain and gut. In summary, loss of tryptophan has promoted a highly branched, unmyelinated neural network, and a plethora of specific receptors to maximize serotonin’s actions.

### 5-HT function

Plants do not have neurons or muscles, but they are nevertheless capable of limited movement by rotating their leaves towards the light and sending their roots deep into the soil to capture H<sub>2</sub>O and nitrogen. In multicellular plant organisms, growth and mitosis are modulated by tryptophan-derived molecules, including serotonin. Furthermore, with the increase in organic complexity, these molecules, in particular auxin, evolved homeostatic functions for effectively capturing and transporting solar energy and integrating plant rhythms and organism physiology. The plants developed effective transport systems for delivering tryptophan-based molecules from one region to another (e.g., leaf to root), depending on need (Mauseth, 2008). These two methods of producing movement, mitosis and maturation of plant cells, are similar to that seen in unicellular organisms and fungi (Eckert *et al.*, 1999). Auxin and other tryptophan regulate the rapid tracking of leaves toward the shifting source of light. The movements of both leaves and roots depend on compounds similar to serotonin, such as auxin (Ivanchenko *et al.*, 2008). The turning of the leaf to its source of energy depends on the rearrangement of the cell’s cytoskeleton inside the leaf cells. In the root, the emersion into the soil is produced by regulating cell division and maturation. Serotonin, auxin and melatonin are involved in ion signaling in the dedifferentiation and differentiation of plant cells (Jones *et al.*, 2007). Auxin is the single most important trophic factor in plants (Perrot-Rechenmann *et al.*, 2002). Serotonin and melatonin have diurnal and seasonal rhythms in their synthesis and function in plants based on availability of solar energy. Thus, many of the transport and receptor mechanisms for serotonin and related molecules are established prior to the appearance of neurons. The actions of serotonin on the cell cytoskeleton and

differentiation forecast the actions of serotonin in neuronal development and adult neuroplasticity in mammals (Azmitia, 1999).

Serotonin acquired many new functions in animals as the animals developed more complex processes. Serotonin-producing cells served a defense mechanism (stinging) in Cnidaria (coral) and in many Arthropoda (insects) (Horen, 1972; Weiger, 1997). In lower animals, serotonin neurons are primarily sensory neurons (activated by external stimuli), and influence food intake, defense withdrawal, and complex locomotor actions such as swimming (e.g., in sea urchins, Echinodermata) (Yaguchi and Katow, 2003). In the worm ganglia (Annelids), serotonin is first found in interneurons, which permits better regulation of complex behaviors such as swimming (Kristan and Nusbaum, 1982) and possibly learning and memory (Moss *et al.*, 2005). In *Caenorhabditis elegans* (Nematodes), 5-HT is involved in modulating feeding behavior by rapidly altering a chemosensory circuit (Chao *et al.*, 2004). The involvement of serotonin is also directed at neurons. The serotonin released from an apical ganglion interacts with specific neuronal receptors to increase or decrease the firing rate of its target cells involved in sensory and motor processing (Marois and Carew, 1997). Actions of serotonin on sexual activity and reproduction are evident (Boyle and Yoshino, 2005). In addition, serotonin changes cAMP and Ca<sup>2+</sup> levels in its target neurons, influences their transcription rate and modifies cell morphology (Pettigrew *et al.*, 2005).

The actions of serotonin thus extend from that of antioxidant through morphogenesis and ascend to being involved in complex behaviors such as an organism’s position in a social hierarchy. Serotonin in lobsters (Arthropods) regulates socially relevant behaviors such as dominance-type posture, offensive tail flicks, and escape responses (Kravitz, 2000). This action of serotonin may be through the 5-HT<sub>1A</sub> receptor (Sosa *et al.*, 2004). 5-HT-regulated social and mental behaviors increased in number and complexity as these functions became more advanced and complicated. The many reports of increased social dominance in primates (Edwards and Kravitz, 1997) and improved mood and confidence in social interactions in humans after using drugs which increase serotonin levels are well documented (Kramer, 1993; Young and Leyton, 2002). In these higher animals, 5-HT continues in its role of a homeostatic regulator in adjusting the dynamic interactions of these many functions within the organism, and how the organism interacts with the outside world.

### Trophic

The actions of serotonin in Metazoa begin very early in development. They are seen at both the blastula and gastrula stages, as noted by the appearance of serotonin

receptors in the blastula stages. In Mollusca, serotonin is involved in the determination of the animal pole during early blastula stages (Buznikov *et al.*, 2003). Application of para-chlorophenylalanine (PCPA, a tryptophan hydroxylase inhibitor) interferes in morphogenesis by arresting gastrulation, which results in the disintegration of embryos. At lower concentrations of PCPA, retarded morphogenetic movements were observed that resulted in malformations in the anterior parts of the embryos and yolk granule degradation in the notochord (Hämäläinen and Kohonen, 1989). In mammals, the actions of serotonin on the developing fetus are felt from the time of conception due to the circulating serotonin in the plasma of the mother (Côté *et al.*, 2007). Serotonin neurons are formed very early in gestation in vertebrates (Lidov and Molliver, 1982; Wallace and Lauder, 1983; Okado *et al.*, 1989). Peripheral tissue also expresses cells which contain serotonin. For example, the mast cells (neuroendocrine) of the lung contain serotonin in the fetus (Kushnir-Sukhov *et al.*, 2006). It is logical to assume that if serotonin made a very early phylogenetic appearance, then it should also make a very early ontogenic appearance. Plant seeds and animal embryos have the highest levels of serotonin.

By increasing cAMP and P-CREB, serotonin mediates a trophic response that may underlie both maturation and memory formation in aplysia (Glanzman *et al.*, 1990). Thus, in much the same way as serotonin and its derivatives influence the process and organelles of photosynthesis to move in order to track the source of light, in animals serotonin influences the morphology of sensory and motor neurons involved in neuronal networking in order to track the source of relevant stimuli. The changes in neuronal morphology are particularly intriguing, because they affect neuronal connectivity in much the same way as has been proposed for vertebrates. Even a relatively brief removal of serotonin from the brain of vertebrates results in loss of spine, dendritic profiles and synapses (Yan *et al.*, 1997; Okado *et al.*, 2001). This topic of neuroplasticity has been extensively reviewed by the current authors (Azmitia, 2001, 2007; Azmitia and Whitaker-Azmitia, 1991, 1997; Jacobs and Azmitia, 1992).

In mammals, serotonin has evolved a trophic relationship with glial cells. High-affinity receptors have been identified on astrocytes and Schwann cells from rodents and primates (Hertz *et al.*, 1984; Whitaker-Azmitia and Azmitia, 1986; Gaietta *et al.*, 2003). One function is for astrocytes to provide serotonergic neurons with tryptophan (Pow and Cook, 1997). The serotonin receptors on astrocytes can also release the neurite extension factor S100B, and glucose (Azmitia, 2001). Serotonin application induces glial-derived neurotrophic factor (GDNF) mRNA expression via the activation of fibroblast growth factor receptor 2 (FGFR2) (Tsuchioka *et al.*, 2008). Activation of

serotonin receptors also promotes the development of glial cells in the brainstem of rats (Tajuddin *et al.*, 2003).

The recruitment of secondary cells to amplify serotonin's trophic actions emerged in animals. Astrocytes are found in vertebrates, and in *C. elegans* and drosophila. These supportive cells may have appeared even earlier. Using antibodies against a myelin marker and an astrocytic marker, evidence for glial cells was found in moths (Arthropoda) and aplysia (Roots, 1981). The emergence of these cells as targets for serotonin is what Brodie and Shore envisioned in 1957 when they termed the serotonin system the 'trophotrophic system'. Serotonin has trophic functions (mitosis, apoptosis, differentiation and metabolism), directly and through astrocytes, the other major cellular system in the brain, by receptor-mediated changes in glucose availability and trophic factor release. These actions are considered to be significant in the development and aging of the brain (Azmitia, 1999). Serotonin can in fact be considered to be important for the development and maturation of the entire organism, since serotonin and its receptors are found throughout the body – see Hansen and Witte, 2008 (gut), Wasserman, 1980 (lung), Raymond *et al.*, 1993 (kidney), Hagmann *et al.*, 1992 (liver) and Nordlind *et al.*, 2008 (skin).

The idea that serotonin functions as a trophic factor in vertebrate brains requires a new concept for how serotonin can be most efficiently distributed from axons. Traditionally, neurotransmitters are transported by the axon to a specific synaptic site where the neurotransmitter is released. This is seen for a proportion of the serotonin axons (Muller *et al.*, 2007). There were major discussions regarding whether serotonin could also function by diffusion from unmyelinated axonal varicosities on to non-synaptic sites (Beaudet and Descarries, 1978), and the controversy was settled by accepting the idea of diffuse release, as well as acknowledging that many of the receptor targets of serotonin are on non-neuronal cells. For example, in the rat brain, serotonin axons course through the lateral and III ventricles along ependymal cells (Møllgård and Wiklund, 1979). Serotonin fibers can be considered to be a 'drip irrigation system' for the brain. As long as the axons are intact, serotonin is efficiently released throughout the brain. In old age and in neurodegenerative diseases, serotonin axons in the human brain degenerate (Azmitia and Nixon, 2008).

#### *Seasonal affective disorder and suicides*

Dysfunctions in brain serotonin are implicated in many mental disorders, such as autism, Down's syndrome, anorexia nervosa, anxiety and depression. There are nearly 10,000 papers dealing with serotonin and various diseases ranging from alcohol addiction (Martinez *et al.*, 2008) to herpes zoster (Ohshima *et al.*, 2004). The relationship

between serotonin and depression is cited in over 13,000 papers, with 1750 citations since 2007. Furthermore, a strong correlation exists between brain serotonin levels, depression and suicide, with the first paper in this area written over 40 years ago (Shaw *et al.*, 1967). Those attempting suicide had significantly lower levels of 5-HIAA in the CSF compared to controls (Mann *et al.*, 1996). PET studies indicate that the 5-HT<sub>2A</sub> receptor is altered in depressed suicide attempters (Audenaert *et al.*, 2006). A decrease in serotonin has serious consequences on normal brain homeostasis, both structural and functional, and influences a person's desire to continue living. It is surprising to learn that sunlight has dramatic actions on the brain serotonin system of humans.

A seasonal variation in affective disorders was reported several decades ago (Videbech, 1975), and has certainly been noted from the earliest times of recorded history. All Northern hemispheric cultures since the Mesopotamians have developed special holidays to mark the nadir of light on Earth, and celebrations to counter winter's gloom (for example, Makar, Sankranti, Saturnalia, and Dong Zhi) (Count and Count, 2000). Seasonal affective disorder (SAD) consists of recurrent major depressive episodes in the fall/winter with remissions in spring/summer, and is effectively treated with serotonin drugs and/or light therapy (Westrin and Lam, 2007). Treatment with light therapy or antidepressant medication is associated with equivalent marked improvement in the assessment of psychosocial functioning and life quality. There was no significant difference in measures in 96 SAD patients receiving 8 weeks of treatment with either (1) 10,000-lux light treatment and a placebo capsule, or (2) 100-lux light treatment (placebo light) and 20 mg fluoxetine (Michalak *et al.*, 2007). Several studies have confirmed that patients respond favorably to light therapy (Yerevanian *et al.*, 1986; Stewart *et al.*, 1991; Rao *et al.*, 1992).

Light therapy has effects on serotonin parameters in humans. It has been shown that blood serotonin increases in healthy subjects and patients with non-seasonal depression after repeated visible light exposure. Blood samples from jugular veins in 101 healthy men showed that turnover of serotonin by the brain was lowest in winter, and directly related to the prevailing duration of bright sunlight (Lambert *et al.*, 2002). The production of serotonin measured by this procedure increased rapidly with exposure to increased luminosity. Serotonin levels were higher on bright days no matter what the time of year, and the amount of serotonin present reflected the hours of sun exposure on a particular day – conditions the day before had no effect. In a group of patients with a history of SAD, significantly lower plasma bipterin and tryptophan levels were measured that increased after light therapy (Hoekstra *et al.*, 2003).

A seasonal rhythm in plasma serotonin transporter in normal subjects was first demonstrated over 25 years ago (Whitaker *et al.*, 1984). There was a significant reduction in the Hamilton Depression Rating Scale (HAMD21) score after therapy vs before treatment, and the K<sub>d</sub> for citalopram binding was significantly higher after phototherapy than before treatment (Swiecicki *et al.*, 2005). In agreement with the previous work, binding studies of 5-HTT show that this protein is in a sensitized state during depression in SAD, and normalizes after light therapy and in natural summer remission (Willeit *et al.*, 2008). Phototherapy had a significant influence on both the measured serotonin transport parameters (B<sub>max</sub> and K<sub>d</sub>).

This suggests that daily light therapy has a sound basis in biology and makes evolutionary sense.

Blue light is effective at increasing tryptophan absorption during photosynthesis in chloroplasts, and this light is efficient at treating patients suffering from SAD. As mentioned with the plant chloroplast system, it appears in human studies that blue light might be the most effective. Blue light can suppress melatonin levels and aid in circadian phase shift. Light therapy is effective at significantly reducing Hamilton Depression Rating Scale (SAD Version) when a narrow band of blue light (468nm) is used (Glickman *et al.*, 2006). The UV-A spectrum does not increase the antidepressant response of light therapy, and clinical application of light therapy should use light sources that have the UV spectrum filtered (Lam *et al.*, 1992). Light therapy relieves suicidal ideation in patients with SAD consistent with overall clinical improvement. Emergence of suicidal ideas or behaviors is very uncommon with light therapy (Lam *et al.*, 2000). It has been proposed that the lighting standards in the home and workplace should be re-evaluated on the basis of new knowledge regarding the neurobiological effects of light (Jacobsen *et al.*, 1987). This might be considered one of the first steps taken by a society to achieve conditions conducive to enhancing serotonin function in the general population, and an acknowledgement of serotonin's special relationship with sunlight that began to emerge at the beginning of life on Earth (Figure 7).

## Summary

Sunlight has beneficial effects on the serotonin system and the mood and stability of humans. This is consistent with the idea that serotonin is involved in homeostasis in humans (Azmitia, 2001) and contributes to the emergence of mind (Azmitia, 2007). What is surprising is the consistency of serotonin's function throughout evolution. The indole ring of tryptophan was the first and principal

**Figure 7** The evolutionary relationship between sunlight and the amino-acid tryptophan and its major derivatives: serotonin, melatonin, auxin and NADH. In addition, the connections of certain tryptophan containing proteins are illustrated: chlorophyll, rhodopsin and 5-HT<sub>1A</sub> receptor. These relationships began in the earliest eukaryotic cells and continue in humans.

means of converting sunlight into biological energy. In the simplest cells, in the presence of sunlight, serotonin and related tryptophan derivatives function as a powerful antioxidant and serve to help organisms to maintain homeostasis, regulate differentiation and promote cell division. The actions of serotonin have consistently been beneficial for the survival of the species throughout early periods of evolution, and for the growth of the organism from the earliest times of ontogeny. This action is maintained even though the availability of tryptophan, needed to produce serotonin, was shut down in animals. The main strategy used by animals is to become voracious consumers of tryptophan-containing plants and animals. In vertebrates, a sophisticated delivery system in the blood was developed to deliver tryptophan throughout the body so serotonin could be synthesized in sufficient quantities to meet its needs. Serotonin is distributed from plasma, neighboring mast cells, and specialized serotonin neurons. In mammals, the expression of serotonin receptors occurs at the earliest stages of ontogeny and is activated by circulating plasma serotonin from the mother. In the early stages of brain development, serotonergic neurons formed in the midbrain and immediately sent out extensive fibers to the forebrain. Serotonin-producing neurons grew complex axonal plexuses of unmyelinated axons dispensing serotonin by a 'drip irrigation' method. Serotonin-specific receptors proliferated in animals, with over a dozen types distributed in every cell and in every organ.

Serotonin, an important tryptophan derivative, has continued to maintain a central position in the evolution (phylogeny) and development (ontogeny) of organisms, from fungi to humans. It is important to recognize that loss of serotonin in the human brain, a major factor in suicides, means loss of synapses and retraction of dendrites and spines (Azmitia, 2001). Seasonal affective depression

and suicidal ideation can be treated with light therapy, which is intended to mimic the beneficial effects of natural sunlight. This chapter has followed an evolutionary path from tryptophan absorption of light in photosynthesis to serotonin's actions in treating seasonal affective disorder. All cells and organs of the body, and especially of the brain, are affected by the serotonin system. The actions of sunlight may be the magic elixir to help maintain homeostasis between body and mind, improve social interactions, and create harmony among the phyla.

## Acknowledgements

I am indebted to Dr. Patricia Whitaker-Azmitia for her comments during the preparation of this manuscript. I also acknowledge the many serotonin researchers whose work has inspired me to focus my career on a single brain chemical. Funding for this research was provided by a New York University Challenge grant.

# Genetic Organization of the Serotonergic System

Ursula M. D'Souza\* and Ian W. Craig

*MRC Social, Genetic and Developmental Psychiatry (SGDP) Centre, Institute of Psychiatry, King's College London, London, UK*

**Abstract:** The serotonergic system consists of a number of genes and includes seven subfamilies of serotonin receptors (*5-HT<sub>1-7</sub>*), with each subfamily revealing several subtypes. The system also includes tryptophan hydroxylase (*TPH-1* and *TPH-2*) and monoamine oxidase (*MAO*) enzymes which are involved in synthesis and degradation of serotonin, respectively. Furthermore, serotonin transporter (*SERT*, *5-HTT*) is an important protein in the scheme as it controls the amount of serotonin in the synapse. Brain-derived neurotrophic factor (*BDNF*) is included in this system, as it is known to modulate serotonin transporter function. Each of the genes and/or gene family is described in terms of their exon-intron organization, chromosomal localization, any alternative splice variants, and 5'-flanking and promoter regions. Interestingly, most of these genes have been implicated in neuropsychiatric disorders; therefore, a discussion has been provided on significant functional polymorphisms that are associated with the phenotypes of interest. In general, all genes of the serotonergic system are organized into exons and introns except for the *5-HT<sub>1</sub>* family of serotonin receptors, which are intronless and encoded by a single exon. Alternative splice forms have been identified in the *5-HT<sub>2C</sub>*, *5-HT<sub>3A</sub>*, *5-HT<sub>4</sub>*, *5-HT<sub>7</sub>*, *TPH-1*, *5-HTT* and *BDNF* genes, whereas RNA editing isoforms are only observed with the *5-HT<sub>2C</sub>* receptor gene. The promoter and 5'-flanking regions have been characterized for the *5-HT<sub>1A</sub>*, *5-HT<sub>2A</sub>*, *5-HT<sub>2C</sub>*, *5-HT<sub>3B</sub>*, *5-HT<sub>4</sub>*, *5-HT<sub>7</sub>*, *TPH-1*, *TPH-2*, *5-HTT*, *MAOA* and *BDNF* genes, with transcription factors (DNA binding proteins) identified in some of the genes to further elucidate transcription regulation. Evidently, the diverse and complex genetic structure/organization and regulation of the serotonin system is associated with the key actions as an important monoamine neurotransmitter in the central nervous system.

**Keywords:** serotonin, gene structure, transcriptional, gene expression, alternative splice variants.

## Introduction

Serotonin (5-hydroxytryptamine; 5-HT) is a biogenic monoamine and an important neurotransmitter/neuromodulator in the central and peripheral nervous system, where it plays a role in several behavioral functions, including mood, sleep cycles, aggression, appetite and learning (Veenstra-VanderWeele *et al.*, 2000; Mohammad-Zadeh *et al.*, 2008). It has been implicated in a wide range of neuropsychiatric conditions, including depression, anxiety disorders, obsessive-compulsive disorders, psychosis, eating disorders, and substance abuse and dependence (Lucki, 1998; Lesch, 2001). Serotonin is produced in two steps; first, the essential amino acid tryptophan is hydroxylated to 5-hydroxytryptophan (5-HTP) by tryptophan hydroxylase (TPH). In the second step, 5-HTP is decarboxylated to form 5-HT by the enzyme

L-aromatic amino acid decarboxylase. The primary catabolic pathway for serotonin is by the enzyme monoamine oxidase (MAO). This is a ubiquitous enzyme that exists in two major forms, MAO-A and MAO-B. Both are present in the brain, and the latter preferentially in serotonergic neurons; however, MAO-A has a higher affinity for serotonin as substrate (see, for example, Shih and Thompson 1999; see also Chapter 2.4 of this volume). Furthermore, the serotonin transporter (5-HTT) which is located on the presynaptic membrane is important in controlling the availability of serotonin in the synaptic cleft.

The diverse effects of serotonin are mediated by several 5-HT receptors. It was originally proposed by Gaddum and Picarelli that these receptors were broadly divided into 'D' and 'M' groups, based on the differential sensitivity of guinea-pig ileum 5-HT-induced contraction to some drugs. However, a new classification was later derived based on radio-ligand binding studies using agonists and antagonists (Bradley *et al.*, 1986; Peroutka, 1998). They proposed that there are three main groups, namely 5-HT<sub>1</sub>, 5-HT<sub>2</sub> and 5-HT<sub>3</sub>, each recognizing different synthetic

ligands. However, with the discovery of molecular biology approaches, the nomenclature has evolved into an accepted classification which indicates seven subfamilies of serotonin receptors (5-HT<sub>1-7</sub>), based on their structural and functional properties, with each subfamily comprising specific subtypes (Hoyer *et al.*, 1994, 2002; see also Chapter 1.6 of this volume). The complicated history of the discovery of genes and identification of ligand-binding sites of some of these subtypes resulted in a cumbersome and confusing nomenclature where different researchers used different terminologies. Thus the serotonin Club Nomenclature Committee revised the nomenclature to enable consistency and consolidation. To this effect, the 5-HT<sub>ID $\alpha$</sub>  receptor subtype was renamed the 5-HT<sub>ID</sub> receptor and the 5-HT<sub>ID $\beta$</sub>  receptor renamed the 5-HT<sub>I $\beta$</sub>  receptor. Additionally, the 5-HT<sub>IC</sub> receptor was renamed 5-HT<sub>2C</sub>, the 'classical' 5-HT<sub>2</sub> receptor known as the 5-HT<sub>2A</sub> receptor, and the 5-HT<sub>2F</sub> receptor called the 5-HT<sub>2B</sub> receptor. For the sake of clarity, the chapter will use the current names of these particular receptor subtypes.

This chapter aims to describe the organization of the genes mentioned above that encompass the serotonergic system. Each gene and gene family will be described in separate sections detailing its gene structure (exon-intron organization), chromosomal localization, splice variants, 5'-flanking and promoter regions, and any significant functional polymorphisms that are associated with psychiatric disorders. Additionally, information on the distribution and second messenger responses of the serotonergic genes will only be covered in brief, as these topics have been reviewed extensively elsewhere (Peroutka, 1998; Barnes and Sharp, 1999; Veenstra-VanderWeele *et al.*, 2000; Lesch, 2001; Hoyer *et al.*, 2002; Cowen, 2007).

In general, the exon (coding regions) and intron (noncoding DNA sequences) boundaries of a gene are elucidated using molecular biology techniques involving cDNA and DNA cloning, and readers are referred to standard textbooks on this topic (Brown, 1999). Following the isolation of a gene, it is necessary to characterize its 5'-flanking and promoter region(s) to determine the transcription initiation site and the location of any exons in the untranslated region, and to identify any upstream regulatory sequence. Several molecular biological methods are used for these analyses and include 5' Rapid Amplification of cDNA ends (5' RACE), genomic walking, primer extension, RNase protection and S1 nuclease assays (Carey and Smale, 2000). Strategies for elucidating control regions involve the generation of serial 5' deletion plasmid constructs fused with a reporter gene such as luciferase or chloramphenicol acetyl transferase (CAT). These constructs are transiently transfected into

mammalian cell lines to determine transcriptional activity of the deletion fragments *in vitro*, or they can be used to generate transgenic mice and determine *in vivo* effects at a brain and behavioral level. Furthermore, electrophoretic mobility assays, DNase I footprinting and yeast one-hybrid studies have focused on identifying which DNA binding proteins (transcription factors) interact within the regulatory domains of several of the target genes.

The topics on gene structure, transcriptional gene regulation and gene expression have been reported comprehensively, and thus are not described here (Beebee and Burke, 1992; Mouradian *et al.*, 1994; Latchman, 1998; Carey and Smale, 2000; Brown and Brown, 2002; D'Souza *et al.*, 2003). Recent discoveries on other levels of gene regulation have been published, and include RNA interference, which is involved in gene silencing and non-coding RNA (ncRNA), or small RNAs that play a role in several pathways that also silence genes (Mattick and Makunin, 2006; Chu and Rana, 2007). Moreover, as DNA is packaged into a nucleoprotein complex known as chromatin, understanding this structure in addition to histone acetylation and DNA methylation as epigenetic modifications associated with heritable changes in gene expression has become a significant topic of current research (Vaissiere *et al.*, 2008).

## Subfamilies of 5-HT receptors

### 5-HT<sub>1</sub> receptor genes

The 5-HT<sub>1</sub> class of serotonin receptors consists of five receptor types with 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>ID</sub> characterized by a high affinity for 5-carboxamido-tryptamine, whereas 5-HT<sub>1E</sub> and 5-HT<sub>1F</sub> are characterized by a low affinity for this synthetic agonist (Lanfume and Hamon, 2004). All five subtypes have nanomolar affinity for the endogenous ligand indolamine and couple preferentially, but not exclusively, to G<sub>i/o</sub> to inhibit adenylate cyclase (Hoyer *et al.*, 2002). The genes encoding the 5-HT<sub>1</sub> receptors have been cloned in both rodents and humans, and found to belong to the superfamily of G-protein coupled receptors having the characteristic seven transmembrane domains. The 5-HT<sub>1A</sub> receptor gene was one of the first of the family to be cloned in rat (Albert *et al.*, 1990; Fujiwara *et al.*, 1990) and in human (Kobilka *et al.*, 1987; Fargin *et al.*, 1988; Stam *et al.*, 1992; Chanda *et al.*, 1993). It was found to be intronless, and encoded by a single exon. The receptor gene is located on chromosome 5q11.2-q13 in humans (Kobilka *et al.*, 1987; Hoyer *et al.*, 1994) and on chromosome 13 in mice (Oakey *et al.*, 1991). The human and rat gene encodes predicted proteins of 421 and 422 amino acids, respectively, which share 89 percent

homology at the amino acid level (Kobilka *et al.*, 1987; Fargin *et al.*, 1988; Albert *et al.*, 1990). The rat  $5\text{-HT}_{1A}$  receptor mRNA distribution in rat brain was comparable with the distribution pattern of the receptor's ligand binding sites, with highest mRNA expression in septum and hippocampus (Albert *et al.*, 1990). In general the  $5\text{-HT}_{1A}$  receptors are widely distributed in the brain, and in the raphe nuclei they act as autoreceptors to inhibit cell firing, whereas in limbic structures, especially the hippocampus, they serve as postsynaptic receptors (reviewed in Hoyer *et al.*, 2002; see also Chapter 1.6 of this volume). The primary signal transduction pathway of the  $5\text{-HT}_{1A}$  receptor is via inhibition of adenylyl cyclase (reviewed in Raymond *et al.*, 1999; Lesch, 2001). However, there is evidence showing that activation of the receptor leads to increased potassium conductance, and in some cell types to an increase in intracellular calcium (reviewed in Cowen, 2007).

The 5'-flanking and promoter regions of the mouse and human  $5\text{-HT}_{1A}$  receptor gene have been found to lack TATA box elements, but are rich in guanine and cytosine residues (Parks and Shenk, 1996). These 5'-flanking regions have 63 percent sequence identity, and consist of a guanine-cytosine-rich DNA sequence motif that interacts with the MAZ (Myc associated zinc finger) (Pur-1, Zif87) protein at four sites in HeLa (human cervical adenocarcinoma) cell nuclear extracts. However, three of the four MAZ binding sites were also shown to interact with the transcription factor Sp1, suggesting that MAZ and Sp1 both participate in regulating expression from the  $5\text{-HT}_{1A}$  receptor gene promoter (Parks and Shenk, 1996). Further analysis of the murine  $5\text{-HT}_{1A}$  receptor gene promoter *in vitro* and *in vivo* was undertaken in which upstream sequences extending to -4.5, -5.5 and -20 kb were examined for activity in cell culture and transgenic animals (Ansorge *et al.*, 2004). These promoter fragments were found to be active in  $5\text{-HT}_{1A}$  receptor mRNA-positive cells (neuronal cell line, mouse neuroblastoma/rat glioma hybrid NG108-15) and inactive in  $5\text{-HT}_{1A}$  receptor mRNA-negative cells (neuronal-like cell line, PC12 (rat adrenal pheochromocytoma) and non-neuronal cell line, COS-7 (African green monkey kidney, SV40 transformed). In adult mice these promoter fragments directed expression of the gene in specific brain regions and in cells with endogenous  $5\text{-HT}_{1A}$  receptor gene expression.

Genetic studies have focused on identifying a polymorphism, which is the existence of two or more alleles at significant frequencies (at least 1 percent) in the population and/or disease phenotypes, where an allele is one of several alternative forms of a gene or DNA sequence at a specific chromosomal location (locus) (see Strachan and Read, 1996; Plomin *et al.*, 2000). A functional SNP (single nucleotide polymorphism) (C-1019G) in the promoter

region of the  $5\text{-HT}_{1A}$  receptor gene has been found to be associated with depression, suicide and panic disorder (Arias *et al.*, 2002; Serretti *et al.*, 2004), and recently with higher geriatric depression scale (GDS) scores (Lenze *et al.*, 2008). In serotonergic raphe RN46A cells, the human transcription factor Deaf-1 (nuclear deformed epidermal autoregulatory factor-1) repressed  $5\text{-HT}_{1A}$  receptor gene expression at the -1019C allele but not the -1019G allele. However, in non-serotonergic cells (septal SN48, neuroblastoma SK-N-SH and neuroblastoma/glioma NG108-15 cell lines) that express  $5\text{-HT}_{1A}$  receptors Deaf-1 enhanced  $5\text{-HT}_{1A}$  promoter activity at the -1019C allele but not the -1019G allele (Czesak *et al.*, 2006). These results suggest that cell-specific regulation by Deaf-1 could underlie region-specific alterations in  $5\text{-HT}_{1A}$  receptor expression in different mood disorders.

Transcriptional initiation and regulation of the rat serotonin  $5\text{-HT}_{1A}$  receptor gene was characterized revealing a major site of transcriptional initiation located 58 bp downstream from a consensus TATA element (Storring *et al.*, 1999). This study also showed, using  $5\text{-HT}_{1A}$ -negative (pituitary GH4C1, L6 myoblast and C6 glioma) and  $5\text{-HT}_{1A}$ -positive (murine SN-48 and rat raphe RN46A) cell lines, that TATA-driven expression of the  $5\text{-HT}_{1A}$  receptor gene is regulated by a novel proximal tissue-specific enhancer region, a non-selective promoter and a distinct upstream repressor region. Furthermore, a 14-bp element was identified in the 5'-flanking region of the  $5\text{-HT}_{1A}$  receptor gene that mediates transcriptional repression in raphe cells ( $5\text{-HT}_{1A}$  receptor expressing cells), and an additional 12-bp sequence identified in  $5\text{-HT}_{1A}$  receptor-negative cells that represses the expression of the gene (Ou *et al.*, 2000). The novel DNA binding protein Freud-1 (5' repressor element under dual repression binding protein-1) was found to bind to the 14-bp 5' repressor element of the  $5\text{-HT}_{1A}$  receptor gene and regulate the gene in neurons in a calcium-dependent manner (Ou *et al.*, 2003). More recently, there is evidence demonstrating that the long isoform of Freud-1 is the major isoform that regulates the human  $5\text{-HT}_{1A}$  receptor gene (Rogaeva and Albert, 2007). Furthermore, previous studies have shown that the rat  $5\text{-HT}_{1A}$  receptor gene is regulated by corticosteroids (Meijer *et al.*, 2000; Wissink *et al.*, 2000).

The classification of the  $5\text{-HT}_{1B}$  and  $5\text{-HT}_{1D}$  receptor subtypes was necessary following the discovery of related genes within the  $5\text{-HT}_1$  receptor family, and reveals a complicated history (Hartig *et al.*, 1996). This was due to the identification of species homologs of a gene (the equivalent gene in different species) which showed high homology at the amino acid level but displayed different pharmacological properties. On the contrary, there was further complexity when two different genes in the same species (intraspecies subtypes) showed only

moderate homology at the amino acid level but displayed indistinguishable pharmacological properties (Hartig *et al.*, 1992). These receptors will be described under the subsequent section here on the 5-HT<sub>1B</sub> receptors, and also under the subdivision reporting on the 5-HT<sub>1D</sub> receptors below. The 5-HT<sub>1B</sub> receptor gene was cloned and characterized from rat brain, revealing a cDNA that contains an 1158-bp open reading frame which encodes a predicted protein having a molecular weight of 43,162 (Voigt *et al.*, 1991). The primary sequence of the gene indicated that it belongs to the 5-HT<sub>1</sub> receptor family, which was confirmed by pharmacological studies. The nucleotide sequence of the rat 5-HT<sub>1B</sub> receptor gene had 45 percent overall identity with the rat 5-HT<sub>1A</sub> receptor gene, and up to 60 percent identity when only the transmembrane domains are considered. *In situ* hybridization studies revealed mRNA expression of the 5-HT<sub>1B</sub> receptor in cells of the dorsal and median raphe nuclei, in agreement with previous findings indicating that this receptor acts as an autoreceptor on 5-HT terminals (Voigt *et al.*, 1991; Hoyer *et al.*, 2002). Interestingly, mRNA expression of the gene in hippocampus, striatum, cortex and cerebellum suggests that the 5-HT<sub>1B</sub> receptor may also have a postsynaptic role (Voigt *et al.*, 1991; Barnes and Sharp, 1999). However, additionally, there is the suggestion that the 5-HT<sub>1B</sub> receptor acts as a heteroreceptor, i.e., a modulatory receptor located on non-5HT terminals (reviewed in Barnes and Sharp, 1999).

The rat 5-HT<sub>1B</sub> receptor gene was also isolated through homology to a human 5-HT<sub>1Dβ</sub> receptor clone, and comparison of the amino acid sequence of the two genes showed a 93 percent overall identity and a 96 percent identity in the transmembrane regions, as well as a strong conservation in the intracellular and extracellular loops (Adham *et al.*, 1991). Additionally, this rat clone encoded a receptor with pharmacological properties matching the human 5-HT<sub>1D</sub> receptor gene, suggesting the 5-HT<sub>1B</sub> receptor gene is the rat homolog of the human 5-HT<sub>1Dβ</sub> receptor gene (see below under the section regarding 5-HT<sub>1D</sub> receptor genes). Cloning of the human 5-HT<sub>1B</sub> receptor gene revealed that it has characteristics of a G-protein coupled receptor and is localized on chromosome 6 at 6q13 (Jin *et al.*, 1992). The gene contains an intronless open reading frame of 1170 nucleotides which encodes a 390 amino acid protein. The isolation of another genomic clone of the human 5-HT<sub>1B</sub> receptor gene revealed it is a homolog of the rat 5-HT<sub>1B</sub> receptor with pharmacological properties of 5-HT<sub>1D</sub> receptors (Hamblin *et al.*, 1992). Thus a new nomenclature was proposed by the International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification (IUPHAR) and the previously known 5-HT<sub>1Dβ</sub> receptor was renamed the human 5-HT<sub>1B</sub> receptor

(Hartig *et al.*, 1996). The 5-HT<sub>1B</sub> receptor negatively couples to adenylyl cyclase under forskolin-stimulated conditions in cell transfection studies (reviewed in Barnes and Sharp, 1999).

Evidence demonstrates that polymorphisms in the 5' untranslated region of the human 5-HT<sub>1B</sub> receptor gene affects gene expression, and that some of these genetic variants are associated with several psychiatric conditions (Duan *et al.*, 2003). Recently, an A/G SNP polymorphism in the 3'UTR of the human 5-HT<sub>1B</sub> receptor gene was found to differentially alter transcriptional activity of a luciferase construct with the A allele being repressed by a microRNA (miR-96) in HeLa cells (Jensen *et al.*, 2008). It also appears to be associated with aggressive phenotypes (Jensen *et al.*, 2008).

The cloning of the originally named 5-HT<sub>1C</sub> receptor gene cDNA revealed that it belonged to the family of G-protein coupled receptors and has a distinct pharmacological profile (Lubbert *et al.*, 1987; Julius *et al.*, 1988). However, following the cloning of the 5-HT<sub>2</sub> receptor family the 5-HT<sub>1C</sub> receptor gene was reclassified as 5-HT<sub>2C</sub> (Humphrey *et al.*, 1993). Thus the 5-HT<sub>1C</sub> nomenclature is no longer used in the literature, and description of this particular gene is provided in the relevant section regarding 5-HT<sub>2</sub> receptor genes.

The cloning of the human 5-HT<sub>1D</sub> receptor gene showed that it contains an intronless open reading frame encoding a 377 amino acid polypeptide with characteristics of G-protein coupled receptors (Hamblin and Metcalf, 1991). The 5-HT<sub>1D</sub> receptor gene was localized to chromosome 1 by southern blot analysis of DNA from a rodent hybrid cell panel (Jin *et al.*, 1992). This first human 5-HT<sub>1D</sub> receptor gene was designated 5-HT<sub>1Dα</sub>, which was followed by the subsequent cloning of a second distinct gene 5-HT<sub>1Dβ</sub> receptor gene which was also intronless (Levy *et al.*, 1992a; Weinshank *et al.*, 1992). However, the human 5-HT<sub>1Dβ</sub> receptor was redefined as the species homolog of the 5-HT<sub>1B</sub> receptor, as its distribution and sequence were similar to the rat 5-HT<sub>1B</sub> receptor. Subsequently, a rat gene was isolated which was homologous to the human 5-HT<sub>1Dα</sub> receptor, having distinct pharmacological properties for a 5-HT<sub>1D</sub> receptor, and thus the 5-HT<sub>1Dβ</sub> receptor was renamed 5-HT<sub>1D</sub> receptor (Hartig *et al.*, 1996). Both genes show strong similarity in sequence, pharmacological properties, inhibition of adenylyl cyclase activity and their mRNA expressed in the cerebral cortex. Interestingly, both the receptors bind to sumatriptan (an anti-migraine drug) with high affinity (Weinshank *et al.*, 1992); however, genetic association studies do not provide evidence for the role of both genes in familial migraine (Racchi *et al.*, 2004) or clinical response to sumatriptan (Mehrotra *et al.*, 2007). Like the 5-HT<sub>1B</sub> receptor, the 5-HT<sub>1D</sub> receptor is located

presynaptically on both serotonin and non-serotonin neurons (reviewed in Barnes and Sharp, 1999).

The human *5-HT<sub>1E</sub>* receptor gene was isolated in several studies (Levy *et al.*, 1992b; Zgombick *et al.*, 1992; Lovenberg *et al.*, 1993). The first isolated the gene from a human placental genomic library by using oligonucleotide probes derived from transmembrane regions of the cloned human *5-HT<sub>1D $\beta$</sub>*  receptor (Zgombick *et al.*, 1992). The deduced amino acid of the isolated genomic clone was identical to the previously isolated but not characterized novel serotonin receptor gene S31 (Levy *et al.*, 1992b). The gene locates to human chromosome 6q14-q15 by *in situ* hybridization (Levy *et al.*, 1994). The nucleotide sequence of human *5-HT<sub>1E</sub>* receptor gene revealed 64 percent homology to the *5-HT<sub>1D $\alpha$</sub>*  and *5-HT<sub>1D $\beta$</sub>*  receptor subtypes in the transmembrane domain regions (Zgombick *et al.*, 1992). The rat *5-HT<sub>1E</sub>* receptor gene was cloned, revealing an intronless open reading frame encoding a 366 amino acid seven-transmembrane domain protein (Lovenberg *et al.*, 1993). Further characterization of the human homolog indicated its encoded protein to have 93 percent overall amino acid identity with the rat sequence. Within the transmembrane domain regions, the human gene showed 52, 59, 65 and 68 percent amino acid identity with the rat *5-HT<sub>1A</sub>*, rat *5-HT<sub>1B</sub>*, rat *5-HT<sub>1D</sub>* and human *5-HT<sub>1E</sub>* receptors, respectively. *5-HT<sub>1E</sub>* receptor mRNA is expressed in cortical regions and caudate and putamen, with lower levels detected in the amygdala and hypothalamic regions, similar to the receptors distribution in the brain, suggesting that the *5-HT<sub>1E</sub>* receptor is located postsynaptically where it mediates inhibits forskolin-stimulated adenylyl cyclase (reviewed in Barnes and Sharp, 1999).

The *5-HT<sub>1F</sub>* receptor gene was originally cloned in the mouse and expressed predominantly in hippocampus, with homology to the *5-HT<sub>1B</sub>*, *5-HT<sub>1D</sub>* and *5-HT<sub>1E</sub>* receptor subtypes (Amlaiki *et al.*, 1992). This was followed by cloning of the human gene, which was found to be intronless and encoded a protein 366 amino acids in length, having a relative molecular weight of 42,000, with distinct pharmacological properties compared with the other *5-HT<sub>1</sub>* receptors. Its protein sequence had 70 percent homology with the *5-HT<sub>1E</sub>* receptor gene, 63 percent homology with the *5-HT<sub>1D $\alpha$</sub>*  and 60 percent homology with the *5-HT<sub>1D $\beta$</sub>*  receptors (Adham *et al.*, 1993). The mRNA expression of the gene was found in human brain but not present in other tissues such as kidney, liver, spleen, heart, pancreas and testes, and its specific mRNA distribution in guinea-pig coronal brain sections revealed expression in hippocampal pyramidal cells, in several thalamic nuclei and in the dorsal raphe nuclei, the latter results suggesting its possible role as an autoreceptor (Adham *et al.*, 1993; Hoyer *et al.*, 2002).

The gene was localized to chromosome 3p12 using a monochromosomal mapping panel, followed by radiation-reduced hybrid mapping and fluorescent *in situ* hybridization (VanDenBrink *et al.*, 1998). Studies in cultured cells showed that the *5-HT<sub>1F</sub>* receptor couples to the inhibition of forskolin-stimulated adenylyl cyclase (reviewed in Barnes and Sharp, 1999).

### *5-HT<sub>2</sub> receptor genes*

The *5-HT<sub>2</sub>* receptors belong to the superfamily of G-protein coupled receptors, and consists of three subtypes: *5-HT<sub>2A</sub>*, *5-HT<sub>2B</sub>* and *5-HT<sub>2C</sub>* (formerly known as the *5-HT<sub>2</sub>*, *5-HT<sub>2F</sub>* and *5-HT<sub>1C</sub>*, respectively) receptors with related molecular structure, amino acid sequence and signaling properties (Hoyer *et al.*, 1994; Leysen, 2004). They couple preferentially to G<sub>q/11</sub> to increase the hydrolysis of inositol phosphates and elevate intracellular calcium (Barnes and Sharp, 1999; Hoyer *et al.*, 2002). The *5-HT<sub>2A</sub>* receptor gene was cloned in rat (Prichett *et al.*, 1988; Julius *et al.*, 1990), hamster (Chambard *et al.*, 1990), mouse (Yang *et al.*, 1992) and human (Saltzman *et al.*, 1991; Stam *et al.*, 1992), and encodes a protein of 471 amino acids. The human *5-HT<sub>2A</sub>* gene is located on chromosome 13q14-q21 (Sparkes *et al.*, 1991), spans over 20kb and consists of three exons separated by two introns (Chen *et al.*, 1992); it is 87 percent homologous with its rat counterpart. *5-HT<sub>2A</sub>* receptor is expressed in several regions in the brain, including cortical areas, caudate nucleus, nucleus accumbens, olfactory tubercle and hippocampus; these areas also correlate with its mRNA distribution, suggesting postsynaptic localization of the receptor in *5-HT* neurons (reviewed in Barnes and Sharp, 1999).

The characterization of the rat *5-HT<sub>2A</sub>* promoter region revealed no TATA boxes or CCAAT sequences (Ding *et al.*, 1993; Du *et al.*, 1994) and the 5'-flanking region of human *5-HT<sub>2A</sub>* receptor gene showed multiple transcription initiation sites (Zhu *et al.*, 1995; Shih *et al.*, 1996) with similar initiation sites found in the mouse and rat genes (Chen *et al.*, 1992; Ding *et al.*, 1993; Du *et al.*, 1994). The promoter activity in the human gene was observed in a fragment that encompassed the transcription initiation sites when transfected into *5-HT<sub>2A</sub>* positive cell lines (SH-SY5Y (human neuroblastoma) and HeLa). Transcription factors Sp1, PEA3 (polyomavirus enhancer activator 3) and E-box binding proteins and two novel transcription factors were found to interact with this DNA fragment (Zhu *et al.*, 1995). PEA3 is the founding member of a subfamily of *ets* oncogenes, whereas the E-box proteins belong to a family of transcription factors that contain a basic helix-loop-helix (bHLH) domain.

Furthermore, two alternative promoters were present with a silencer region just downstream of the second promoter (Zhu *et al.*, 1995).

Polymorphisms in the *5-HT<sub>2A</sub>* receptor gene have been found to be associated with schizophrenia and impulsive behavior (reviewed previously D'Souza and Craig, 2008; Nomura and Nomura, 2006). One of the gene variants is a SNP (A-1438G) located close to the promoter region of the gene, and this was investigated further for functional effects in our previous study (Parsons *et al.*, 2004). The transcriptional activity of the G allele was significantly lower than the A allele when the more downstream promoter was cloned into a reporter gene construct in the presence of an enhancer region (Parsons *et al.*, 2004). The effect was only seen in endogenous *5-HT<sub>2A</sub>* receptor gene expressing SH-SY5Y and HeLa cells. However, no differences were found in allele-specific mRNA expression human cortical tissue (Bray *et al.*, 2004). Furthermore, even though the *5-HT<sub>2A</sub>* receptor gene was found to be differentially expressed in several human *post-mortem* brain regions, the dose-dependent effect on gene expression in relation to the A-1438G SNP did not reach significance (Sugden *et al.*, 2009).

The *5-HT<sub>2B</sub>* receptor gene was first cloned from stomach fundus in mouse (Foguet *et al.*, 1992a) and in rat (Foguet *et al.*, 1992b), the latter gene encoding a protein of 465 amino acids. This was followed by the cloning and characterization of the human *5-HT<sub>2B</sub>* receptor gene (Kursar *et al.*, 1994; Schmuck *et al.*, 1994). The human *5-HT<sub>2B</sub>* receptor cDNA isolated from a library derived from SH-SY5Y cells consisted of an open reading frame encoding 483 amino acids. It had an overall sequence homology of 80 percent and 90 percent within the membrane spanning regions when compared with the sequence of the rat gene (Schmuck *et al.*, 1994). Two introns were found in the human *5-HT<sub>2B</sub>* gene in the same locations of the introns in the mouse *5-HT<sub>2B</sub>* receptor subtypes (Foguet *et al.*, 1992a). However, the human *5-HT<sub>2B</sub>* receptor gene isolated from a human placental genomic library had a single open reading frame encoding a protein of 481 amino acids showing 82 percent overall identity and 91.5 percent identity within the transmembrane domains at the amino acid level compared with the rat *5-HT<sub>2B</sub>* receptor (Kursar *et al.*, 1994). The human *5-HT<sub>2B</sub>* receptor gene was located to chromosome 2q36.3–2q37.1 (Horton *et al.*, 1996; Barnes and Sharp, 1999). The mRNA and protein of the *5-HT<sub>2B</sub>* gene is detected at low levels in the brain compared with that of the *5-HT<sub>2A</sub>* and *5-HT<sub>2C</sub>* receptors; however, its immunostaining is restricted to cerebellum, lateral septum, dorsal hypothalamus and medial amygdala, suggesting a potential functional significance (reviewed in Barnes and Sharp, 1999).

As mentioned in the previous section, *5-HT<sub>2C</sub>* was originally *5-HT<sub>1C</sub>* in the older nomenclature, as they displayed similar pharmacological properties and second messenger systems, indicating that they were structurally related (Lubbert *et al.*, 1987). The *5-HT<sub>2C</sub>* receptor gene was partially cloned in mice (Lubbert *et al.*, 1987), which subsequently led to isolation and sequencing of the full-length clone in rat (Julius *et al.*, 1988), in mouse (Yu *et al.*, 1991) and in human (Saltzman *et al.*, 1991). *5-HT<sub>2C</sub>* receptor gene is different among the members of the *5-HT<sub>2</sub>* receptor family, as it has a different genomic organization with three introns which separate the coding sequence into four exons. The first two introns are at equivalent positions as compared to the introns previously found in the *5-HT<sub>2A</sub>* receptor gene, suggesting a close relationship between the two genes (Stam *et al.*, 1994). The *5-HT<sub>2C</sub>* receptors are widely distributed in cortex, the limbic system and basal ganglia, where they are located postsynaptically; however, there are suggestions it may have a role presynaptically in projections of the habenula (reviewed in Barnes and Sharp, 1999). The *5-HT<sub>2C</sub>* receptor gene was found to map to the human Xq24 chromosome and to mouse chromosome X D-X (reviewed in Barnes and Sharp, 1999). Interestingly, an alternatively splice variant of the *5-HT<sub>2C</sub>* receptor has been identified in the rat, mouse and human, and termed *5-HT<sub>2C-tr</sub>* (Canton *et al.*, 1996; Xie *et al.*, 1996). The sequence of this alternatively spliced form revealed a deletion of the region that codes for the putative second intracellular loop and the fourth transmembrane domain of the *5-HT<sub>2C</sub>* receptor. This deletion results in a frameshift and premature termination, generating a protein of 248 amino acids. The mRNA of the short form is expressed in the same brain regions as the *5-HT<sub>2C</sub>* receptor gene, including the striatum, hippocampus, hypothalamus and olfactory tubercle (Canton *et al.*, 1996); however, its expression is higher in choroid plexus tumors than in normal brain tissue (Xie *et al.*, 1996). Additionally, the *5-HT<sub>2C</sub>* receptor gene is subject to other post-transcriptional modifications such as RNA editing, in which up to five adenosine residues are converted to inosines by double-stranded RNA adenosine deaminase(s) in the region of the receptor that codes for the second intracellular loop to produce up to 24 isoforms in brain with distinct structures and functions (Burns *et al.*, 1997; Fitzgerald *et al.*, 1999; Niswender *et al.*, 1999; Wang *et al.*, 2000; Werry *et al.*, 2008). Interestingly, evidence has shown that editing and splicing processes are correlated, and strongly suggests that RNA editing modulates alternative splicing in cell culture and human brain tissue (Flomen *et al.*, 2004).

Transcriptional regulation of the human *5-HT<sub>2C</sub>* receptor gene has revealed its promoter region to be TATA-less with multiple initiation sites and a 7.3-kb 5'-flanking

region which demonstrates reporter gene transcription activity in SK-N-SH and IMR32 neuroblastoma cells (Xie *et al.*, 1996). The *5-HT<sub>2C</sub>* receptor gene has been associated with obesity (Yuan *et al.*, 2000) and reduced weight gain in subjects treated with antipsychotics (Reynolds *et al.*, 2002) in genetic studies where polymorphisms within the promoter region of the gene have been identified, including the  $-995\text{G/A}$ ,  $-759\text{C/T}$ ,  $-697\text{G/C}$  and GTn microsatellite (dinucleotide polymorphism) at  $-1027\text{bp}$  (Yuan *et al.*, 2000; Reynolds *et al.*, 2002). Two of the haplotypes each consisting of a particular allele of the upstream GTn microsatellite (Z-6) have higher expression relative to the wild type in a mouse embryonal carcinoma (P19) cell line (Yuan *et al.*, 2000). Additionally, haplotypes containing the  $-759\text{C}$  allele showed reduced transcriptional activity compared with haplotypes containing the  $-759\text{T}$  allele in HEK293 (human embryonic kidney) and TE671 (human medulloblastoma) cell lines (Buckland *et al.*, 2005). Furthermore, haplotypes with either  $-759\text{T}$  or  $-697\text{C}$  alleles reduced promoter activity of the gene in SH-SY5Y human neuroblastoma cells (Hill and Reynolds, 2007). However, more recently the GTn microsatellite polymorphism was found not to affect mRNA expression of the *5-HT<sub>2C</sub>* receptor in *post-mortem* brain tissue (Sugden *et al.*, 2009). Other studies have shown that the *5-HT<sub>2C</sub>* mRNA is significantly decreased in *post-mortem* brain from schizophrenics (Castensson *et al.*, 2003), and this change in expression is not related to promoter polymorphisms or neuroleptic drug treatment (Castensson *et al.*, 2005).

### **5-HT<sub>3</sub> receptor genes**

The 5-HT<sub>3</sub> receptors belong to the cys-loop family of pentameric ligand-gated ion channels, whereas all other 5HT receptors are G-protein coupled receptors. These receptors share characteristic features with other members of the ion channel family, including a large extracellular domain containing a conserved cysteine loop, four hydrophobic transmembrane domains, a large intracellular loop between the third and fourth transmembrane regions, and an extracellular C-terminus (Reeves and Lummis, 2002). The ion channel itself is an oligomeric complex consisting of five subunits, and each subunit has a protein structure with four transmembrane domains and a long N-terminal extracellular loop (Niesler *et al.*, 2003; Tzvetkov *et al.*, 2007). To date, five homologous genes coding for the 5-HT<sub>3</sub> receptor subunits (*5-HT<sub>3A</sub>*, *5-HT<sub>3B</sub>*, *5-HT<sub>3C</sub>*, *5-HT<sub>3D</sub>* and *5-HT<sub>3E</sub>*) have been identified in humans (Tzvetkov *et al.*, 2007). However, some of these genes have also been cloned in other species, including rodents. Heteromeric receptors composed of 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> subunits have

been experimentally shown to form functional receptors, whereas the role of the C, D and E subunits remains unclear. The 5-HT<sub>3</sub> receptors are involved in the regulation of gastrointestinal tract motility in the periphery. In the brain, they play an important role in regulation of nausea, vomiting and mental functions, with 5-HT<sub>3</sub> receptor antagonists used in drug abuse and the treatment of withdrawal symptoms (Costall and Naylor, 2004).

The cloning of the murine *5-HT<sub>3A</sub>* receptor gene revealed its organization in 9 exons separated by 8 introns spanning over 12 kb of DNA sequence (Uetz *et al.*, 1994; Werner *et al.*, 1994). Interestingly, the mouse *5-HT<sub>3A</sub>* gene intron–exon organization demonstrated similarities to muscular and neuronal nicotinic acetylcholine receptor genes (Wada *et al.*, 1988). Additionally, an alternative use of exon 9 splice acceptor sites results in the deletion of 6 amino acids in the large intracellular loop between transmembrane 3 and transmembrane 4, therefore generating a short (*m5-HT<sub>3A(a)</sub>* receptor) and a long (*m5-HT<sub>3A(b)</sub>* receptor) isoform of the murine *m5-HT<sub>3A</sub>* receptor (Hope *et al.*, 1993; Uetz *et al.*, 1994; Werner *et al.*, 1994). The *m5-HT<sub>3A(a)</sub>* mRNA expression is about five times higher than the *m5-HT<sub>3A(b)</sub>* mRNA in both neuroblastoma and neuronal tissues (Werner *et al.*, 1994). The long and short isoforms of the *5-HT<sub>3A</sub>* receptor gene were also identified in the rat (Isenberg *et al.*, 1993) and in the guinea pig (Lankiewicz *et al.*, 1998). The coding sequence of the human *5-HT<sub>3A</sub>* receptor gene was initially identified by screening a neuroblastoma library (Maricq *et al.*, 1991), and subsequently its cDNA sequence was further determined in three studies which revealed differences in four amino acid residues and in the 5' and 3' non-coding regions (Belelli *et al.*, 1995; Miyake *et al.*, 1995; Lankiewicz *et al.*, 1998). Additionally, about 84 percent amino acid sequence identity was observed with the mouse *5-HT<sub>3A</sub>* receptor gene (Belelli *et al.*, 1995; Miyake *et al.*, 1995). Further elucidation of the exon–intron organization of the human *5-HT<sub>3A</sub>* receptor gene revealed the gene spans 14.5 kb, and the coding region are separated by 8 introns at identical positions to the murine *5-HT<sub>3A</sub>* receptor gene (Bruss *et al.*, 2000). This confirmed the previously published human *5-HT<sub>3A</sub>* receptor gene cDNA sequence (Miyake *et al.*, 1995). However, the alternative splice acceptor in intron 8 of the murine gene was not present in the human homolog, and all human introns except for intron 5 were longer than their murine counterparts (Bruss *et al.*, 2000). Other alternative splice variants have been identified in humans, revealing that a short h-HT<sub>3A</sub> form is generated through skipping of exon 6, whereas a long form is produced through continuation of intron 7 (Bruss *et al.*, 1988). The human homolog of the mouse *5-HT<sub>3A</sub>* receptor gene was assigned to human chromosome 11 by hybridization to rodent–human hybrid

cell lines (Uetz *et al.*, 1994) and regionally localized to chromosome 11q23.1–q23.2 using fluorescence *in situ* hybridization (Weiss *et al.*, 1995).

The human *5-HT<sub>3B</sub>* receptor gene was cloned using fetal brain and kidney cDNA libraries and found to encode a protein of 441 amino acid residues showing 41 percent amino acid identity with the *5-HT<sub>3A</sub>* receptor subunit (Davies *et al.*, 1999). The human *5-HT<sub>3B</sub>* receptor gene was also cloned from the small intestine cDNA library and the nucleotide sequence revealed a single large open reading frame of 1326bp with 44 percent amino acid identity to the *5-HT<sub>3B</sub>* receptor (Dubin *et al.*, 1999). Interestingly, evidence for the heteromeric assemblies of *5-HT<sub>3A</sub>* and *5-HT<sub>3B</sub>* subunits showed distinct pharmacological properties of the *5-HT<sub>3</sub>* receptor which would have an effect on *5-HT* activation of neuronal excitability and transmitter release (Davies *et al.*, 1999; Dubin *et al.*, 1999). Northern blot analysis and *in situ* hybridization studies demonstrated that the human *5-HT<sub>3B</sub>* mRNA is co-expressed with the *m5-HT<sub>3A</sub>* transcripts in the amygdala, caudate, hippocampus and cerebral cortical areas of the brain, which are also enriched with *5-HT<sub>3</sub>* receptor proteins (Davies *et al.*, 1999; Dubin *et al.*, 1999). The human *5-HT<sub>3B</sub>* receptor gene was found to localize to chromosome 11q23, which is also the position of the *5-HT<sub>3A</sub>* receptor gene (Weiss *et al.*, 1995), and suggests that the homologs arose from a local gene duplication event (Davies *et al.*, 1999).

The *5-HT<sub>3B</sub>* receptor gene was found to have two alternative promoter regions (which lack TATA boxes and CpG island motifs) that control the expression of different *5-HT<sub>3B</sub>* transcripts with variations in the 5' coding sequence in the peripheral and central nervous system. The transcription start sites in the brain were localized 4000bp downstream of the first ATG start codon, and significant promoter activity was located from 1560bp upstream to 93bp downstream of the brain specific transcription start sites (Tzvetkov *et al.*, 2007). Examination of a deletion–insertion polymorphism (–100–102delAAG) in the promoter region of the *5-HT<sub>3B</sub>* receptor gene showed that the deletion allele increases promoter activity *in vitro* with 25 percent and 40 percent higher expression in PC-12 and HEK293 (human kidney transformed) cells, respectively, compared with the insertion construct (Meineke *et al.*, 2008).

The cloned human *5-HT<sub>3C</sub>*, *5-HT<sub>3D</sub>* and *5-HT<sub>3E</sub>* receptor genes were found to be clustered in a subinterval of 100kb on chromosome 3q27; they have restricted expression in the kidney, colon and liver and are widely expressed in the brain (Niesler *et al.*, 2003). The identification of these genes that encode different subunits provides insight to the complexity of the physiological activity of the *5-HT<sub>3</sub>* receptor system. Furthermore, there

is recent evidence of an association of a functional variant in the 3'UTR of the *5-HT<sub>3E</sub>* receptor gene with diarrhea predominant irritable bowel syndrome which was affected by binding of microRNA-510 (Kapeller *et al.*, 2008).

### *5-HT<sub>4</sub> receptor genes*

The *5-HT<sub>4</sub>* receptors belong to the superfamily of G-protein coupled receptors, and couple positively to G<sub>s</sub> to stimulate adenylyl cyclase. They are encoded by a complex gene that spans 700kb and consists of 38 exons which generate 7 carboxyl-terminal variants, termed a, b, c, d, e, f and g, whose sequences differ after the amino acid leucine in position 358 (Leu358). Another variant, referred to as the internal splice variant (h), is characterized by insertion of 14 amino acids into the second extracellular loop of the receptor (Bender *et al.*, 2000; Bockaert *et al.*, 2004). Furthermore, a novel *5-HT<sub>4</sub>* receptor splice variant, *5-HT<sub>4(i)</sub>* has also been identified (Brattelid *et al.*, 2004). The *5-HT<sub>4</sub>* receptors play a role in regulating gastrointestinal tract motility and bladder contraction, and in the central nervous system it is involved in anxiety, memory and cognitive processing (Bender *et al.*, 2000; Maillet *et al.*, 2005).

The *5-HT<sub>4A</sub>* receptor gene was cloned in the rat, showing a distinct pharmacological profile and that it belongs to the superfamily of G-protein coupled receptors (Gerald *et al.*, 1995). It was found to have two splice variants termed r5-HT<sub>4(aL)</sub> and r5-HT<sub>4(aS)</sub> for the long and short forms of the receptor, respectively, which differ in the length and sequence of their carboxyl terminus and gene expression levels in the brain (Gerald *et al.*, 1995). These alternatively spliced variants have been renamed r5-HT<sub>4(a)</sub> and r5-HT<sub>4(b)</sub> for the short and long forms of the receptor, respectively, following recommendations from the IUPHAR receptor nomenclature committee (Hoyer and Martin, 1997). The mouse *5-HT<sub>4(a)</sub>* receptor gene has high homology with the previously cloned rat *5-HT<sub>4(a)</sub>* receptor gene, and it has two splice variants which were expressed in most regions of mouse brain (Claeysen *et al.*, 1996). This is in contrast to the findings in rat, which showed that the long form is widely expressed in brain but the short form is restricted to the striatum (Gerald *et al.*, 1995). Subsequently, the cloning of the human *5-HT<sub>4(a)</sub>* receptor gene from a human brain cDNA library showed that its sequence had strong similarity to the rat *5-HT<sub>4(aL)</sub>* receptor cDNA (Van den Wyngaert *et al.*, 1997). Moreover the cloning of the human *5-HT<sub>4a</sub>* receptor gene from cardiac tissue revealed the h5-HT<sub>4(a)</sub> receptor had 93 percent protein identity with the short form of the rat *5-HT<sub>4(a)</sub>* receptor (Blondel *et al.*, 1997). Three new splice variants of the human *5-HT<sub>4</sub>* receptor were subsequently

identified, which were named h5-HT<sub>4(b)</sub>, h5-HT<sub>4(c)</sub> and h5-HT<sub>4(d)</sub> receptors (Blondel *et al.*, 1998). These variants were also generated by alternative splicing events that occur in the carboxyl terminus of the human h5-HT<sub>4</sub> receptor, just after the amino acid leucine at position 358. The human 5-HT<sub>4</sub> receptor gene was localized to chromosome 5 bands 5q31–5q33 by *in situ* hybridization (Claeysen *et al.*, 1997). Sequence analysis indicates that the h5-HT<sub>4(a)</sub> and h5-HT<sub>4(b)</sub> receptors are human counterparts of the rat 5-HT<sub>4(a)</sub> and 5-HT<sub>4(b)</sub> receptor isoforms, respectively, whereas h5-HT<sub>4(c)</sub> and h5-HT<sub>4(d)</sub> are novel isoforms (Blondel *et al.*, 1998). The carboxyl terminus of h5-HT<sub>4(c)</sub> reveals a high number of phosphorylation sites and the h5-HT<sub>4(d)</sub> isoform produces an ultrashort form of the receptor with a truncation of two amino acids after the splicing site; data showed that the splice variants may differ in signal transduction following receptor activation (Blondel *et al.*, 1998). Similar splice variants in mouse, rat and human brain have been cloned and shown to have different coupling efficiency (Claeysen *et al.*, 1998). Three additional splice variants with shorter carboxyl-terminal sequences have been cloned from different species; these are termed rat 5-HT<sub>4(e)</sub>, mouse 5-HT<sub>4(f)</sub> and human 5-HT<sub>4(g)</sub>. These demonstrate higher capacity for isomerization from the inactive to active conformation of the receptor (Claeysen *et al.*, 1999). Furthermore, the human 5-HT<sub>4(e)</sub> (Mialet *et al.*, 2000) from heart and the human 5-HT<sub>4(a–g)</sub> spliced variants and a novel internal splice variant 5-HT<sub>4(hb)</sub> were cloned from a genomic library, revealing more information on the structure of the human 5-HT<sub>4</sub> gene (Bender *et al.*, 2000). The gene was found to span more than 130kb and consists of 10 exons, with exons 2–5 encoding the most common part shared by all splice variants up to Leu358. The other exons downstream of exon 5 have been named alphabetically to correspond to the previous nomenclature given to the variants obtained by cDNA cloning. The novel splice variant results in the insertion of 14 amino acids in the second extracellular loop of the receptor and has a C-terminal b variant, thus it was termed 5-HT<sub>4(hb)</sub>, which has a different second messenger activation from the other 5-HT<sub>4</sub> receptor isoforms (Bender *et al.*, 2000). Other human 5-HT<sub>4</sub> splice variants have been cloned and characterized, and include the 5-HT<sub>4(n)</sub> from the hippocampus, which contains none of the C-terminal exons (Vilaro *et al.*, 2002), and the 5-HT<sub>4(i)</sub> from pancreas, whose C-terminal does not influence coupling to adenylate cyclase (Brattelid *et al.*, 2004).

The 5'-flanking region and promoter of the 5-HT<sub>4</sub> gene from human placenta was characterized revealing a long (more than 5.1 kb) 5' untranslated region and cell-specific gene expression within –210 to –105 bp in human choriocarcinoma T3M-3 (5-HT<sub>4</sub> receptor positive) and human hepatocellular carcinoma HepG2 (5-HT<sub>4</sub>

receptor negative) cell lines (Hiroi *et al.*, 2001). Additionally, the untranslated exon 1 contains both negative (+112 to +182) and positive (+1 to +11) modulators, suggesting that exon 1 plays a role in the transcriptional regulation of the 5-HT<sub>4</sub> gene. Another study characterized the 5'UTR in human heart and found it to be 3.1 kb in length, containing a novel exon (Maillet *et al.*, 2005). The promoter region of this gene was 1.2 kb in length (–4298 to –3050) in human HeLa and IMR32 (neuroblastoma) cell lines but silent in monkey COS-7 cells, and lacked TATA and CAAT boxes. The enhancer region (–220/–61) in the long 5'UTR region was found to interact with the transcription factor Nkx2.5 (NK2-transcription factor-related 5, also called Csx), which is a member of the NK class of homeo-domain proteins (Maillet *et al.*, 2005).

### 5-HT<sub>5</sub> receptor genes

The 5-HT<sub>5</sub> receptor family consists of two subtypes, known as the 5-HT<sub>5A</sub> and 5-HT<sub>5B</sub> receptors, which belong to the superfamily of G-protein coupled receptors (see Nelson, 2004, for review). This family of 5-HT receptors is the least well understood amongst the serotonin receptor classes. The cDNA sequence of the 5-HT<sub>5A</sub> receptor gene was initially generated from a mouse-brain library with a pharmacological profile similar to the 5-HT<sub>1D</sub> receptor but with distinct intracellular signaling properties and expression pattern (Plassat *et al.*, 1992). Subsequently, the gene was cloned in the rat (Erhlander *et al.*, 1993) and in human (Rees *et al.*, 1994). The human gene, similar to the mouse and rat 5-HT<sub>5A</sub> receptor genes, consists of two coding exons separated by a large intron (positioned in the middle of the third intracellular loop of the receptor) and codes for a protein of 357 amino acid residues. The human 5-HT<sub>5A</sub> receptor has 93 percent nucleotide identity and 84 percent amino acid identity to the cloned mouse 5-HT<sub>5A</sub> receptor, and is expressed in most regions of the brain with little or no expression in peripheral tissues. *In situ* hybridization studies in rat and mouse brain were in agreement regarding the widespread distribution of the gene; however, the transcript was present in the cerebral cortex, the dentate gyrus, the pyramidal cell layer within the hippocampus (CA1–3), the granule cell layer of the cerebellum and the tufted cells of the olfactory bulb (Plassat *et al.*, 1992). The 5-HT<sub>5A</sub> receptor gene was located on mouse chromosome 5 (position 5B) and human chromosome 7q36 (Matthes *et al.*, 1993).

The 5-HT<sub>5B</sub> receptor gene has been cloned in the rat (Erhlander *et al.*, 1993; Wisden *et al.*, 1993) and in the mouse (Matthes *et al.*, 1993), with a distinct ligand-binding profile and specific expression in medial habenula

and hippocampal CA1 cells in adult brain. The gene was located on mouse chromosome 1 (position IF) and human chromosome 2q11-13 (Matthes *et al.*, 1993).

### 5-HT<sub>6</sub> receptor genes

The 5-HT<sub>6</sub> receptor gene is the most recent addition to the 5-HT receptor family, and belongs to the superfamily of G-protein coupled receptors (as reviewed in Woolley *et al.*, 2004). The gene has been cloned in the rat (Monsma *et al.*, 1993; Ruat *et al.*, 1993a), human (Kohen *et al.*, 1996) and mouse (Kohen *et al.*, 2001). The receptor is positively coupled to adenylyl cyclase via G<sub>s</sub> proteins, is expressed abundantly in the caudate nucleus of the brain and has distinct pharmacological properties, including high affinity for atypical antipsychotics such as clozapine. The human 5-HT<sub>6</sub> cDNA has an open reading frame of 1320bp, which is interrupted by two introns in positions corresponding to the third cytoplasmic loop and third extracellular loop, resulting in an apparent frame shift compared to the rat 5-HT<sub>6</sub> receptor gene. It encodes a protein of 440 amino acids with a molecular size of 47kDa. The rat 5-HT<sub>6</sub> receptor gene was re-sequenced using the same clone used by Monsma *et al.* (1993), and the amino acid sequence of the human 5-HT<sub>6</sub> receptor was 89 percent similar to the corrected rat sequence (Kohen *et al.*, 1996). The human 5-HT<sub>6</sub> receptor gene was found to map to 1p35-p36, which overlaps the assignment for the 5-HT<sub>1D $\alpha$</sub>  receptor gene, suggesting a close link between these genes (Kohen *et al.*, 1996). Similar to the human 5-HT<sub>6</sub> receptor gene, the mouse 5-HT<sub>6</sub> receptor gene is 1320bp in length and codes for a protein of 440 amino acid residues and a molecular weight of 47kDa (Kohen *et al.*, 2001). The mRNA expression of the gene is largely present in the central nervous system, and low levels are detected in the stomach and adrenal glands. In the brain the transcripts are present in the striatum, nucleus accumbens, hippocampus, cortex and olfactory tubercle by *in situ* hybridization and northern blot analyses (reviewed in Barnes and Sharp, 1999).

### 5-HT<sub>7</sub> receptor genes

The 5-HT<sub>7</sub> receptor family consists of several alternative splice variants, known as 5-HT<sub>7(a)</sub>, 5-HT<sub>7(b)</sub>, HT<sub>7(c)</sub>, HT<sub>7(d)</sub> and HT<sub>7(e)</sub>. The rat 5-HT<sub>7(a)</sub> receptor gene was isolated from kidney proximal tubule (Shen *et al.*, 1993) and brain (Ruat *et al.*, 1993b), and expressed highly in the hypothalamus, hippocampus and brainstem. In the human, the 5-HT<sub>7(a)</sub> receptor gene was initially identified as the long form of the 5-HT<sub>7</sub> gene (Bard *et al.*, 1993) and later

cloned in brain (Stam *et al.*, 1997). The human 5-HT<sub>7(b)</sub> receptor gene, which has a 13 amino acid truncation that results from a 5-bp insertion that introduces a stop codon, was also isolated (Heidmann *et al.*, 1997; Jasper *et al.*, 1997; Stam *et al.*, 1997). The rat 5-HT<sub>7(b)</sub> receptor cDNA was isolated from a brain library and was found to contain a 5-bp insertion (GTAAG) at an intron splice site which generated an 'in frame' stop codon which shortened the carboxy tail by 13 amino acids (Lovenberg *et al.*, 1993). Further isoforms have been identified and designated as the 5-HT<sub>7(c)</sub> receptor gene in rat, 5-HT<sub>7(d)</sub> receptor gene in human and 5-HT<sub>7(e)</sub> receptor gene in rat (Heidmann *et al.*, 1997; Liu *et al.*, 2001). Both the 5-HT<sub>7(c)</sub> and 5-HT<sub>7(d)</sub> receptor isoforms are generated from the use of two distinct exon cassettes, located within intron 2 of the genes, which result in proteins differing in their carboxyl-terminal ends. The human 5-HT<sub>7</sub> receptor gene was cloned and mapped to chromosome 10q21-q24 (Gelernter *et al.*, 1995) and the identification of a human 5-HT<sub>7</sub> receptor pseudogene has also been reported (Olsen *et al.*, 1997; Qian *et al.*, 1998; Olsen and Schechter, 1999). In mouse, the 5-HT<sub>7(a)</sub> receptor gene was previously cloned (Plassat *et al.*, 1993) and the splice variants m5-HT<sub>7(b)</sub> and m5-HT<sub>7(c)</sub> have been recently identified (Gellynck *et al.*, 2008).

The promoter region of the human 5-HT<sub>7</sub> receptor gene lacks any TATA or CAAT boxes, but is GC rich, regulated by the transcription factors Sp1 and Sp3, and a region 653bp upstream of the ATG start codon demonstrates highest transcriptional activity in both NS20Y (mouse neuroblastoma) and HEK293 cells (Laenen *et al.*, 2007).

### Tryptophan hydroxylase genes

Tryptophan hydroxylase (also known as TrpOHase, or L-tryptophan tetrahydropteridine oxygen oxidoreductase) is the rate-limiting enzyme in the biosynthesis of serotonin that catalyzes the hydroxylation of the essential amino acid tryptophan to 5-hydroxytryptophan. Together with phenylalanine hydroxylase and tyrosine hydroxylase, tryptophan hydroxylase is a member of a family of aromatic amino acid hydroxylases that utilize tetrahydropterins as substrates (Cooper *et al.*, 1996; Fitzpatrick, 1999). 5-HT synthesis in the brain is found mainly in serotonergic neurons of the dorsal raphe nucleus and additionally synthesized in the pineal gland, where it is a precursor in the synthetic pathway of melatonin. Interestingly, there are two genes that code for tryptophan hydroxylase; these are known as *TPH-1* and *TPH-2*. Generally, *TPH-1* mainly catalyzes serotonin synthesis in peripheral organs, and the newly identified tryptophan hydroxylase-2

(TPH-2) is responsible for the synthesis of serotonin in the central nervous system (reviewed in Invernizzi, 2007).

### ***Tryptophan hydroxylase 1 gene (TPH-1)***

The *TPH-1* cDNA was first isolated from the rat (Darmon *et al.*, 1986, 1988) and rabbit pineal glands (Grenett *et al.*, 1987). Interestingly, several *TPH-1* mRNA transcripts have been revealed in rats that differ in the lengths of their 3' (Darmon *et al.*, 1988) and 5' untranslated regions, suggesting different mechanisms of *TPH-1* gene regulation in the pineal gland and brainstem (Delort *et al.*, 1989; Chamas and Sabban, 2002). The two rat mRNA transcripts generated by diversity at the 5'UTR have been designated *TPH-α* and *TPH-β* (having a longer 5'UTR), with expression of *TPH-α* significantly higher than that of *TPH-β* in the pineal gland and raphe nuclei in the brainstem (Delort *et al.*, 1989; Chamas and Sabban, 2002). *TPH-β* has a greater effect than *TPH-α* on translation of the heterologous gene luciferase in PC12 (rat pheochromocytoma) cells, indicating selective regulation of translation efficiency (Chamas and Sabban, 2002). Additionally, the rat gene was cloned from serotonergic neurons in the dorsal raphe nucleus (Kim *et al.*, 1991). In mouse, the gene was cloned from P815 mastocytoma cells, spans 21 kb, consists of 11 exons, and has been localized to the proximal half of chromosome 7 (Stoll *et al.*, 1990; Stoll and Goldman, 1991). Similar to the rat *TPH-1* gene, the coding sequence of the gene in human carcinoid tumor cells was 1332bp and encodes a protein of 444 amino acids of a predicted molecular weight of 50,952 daltons (Boularand *et al.*, 1990). The nucleotide sequence identity was 86.8 percent and 91.2 percent between the human and rat genes (Boularand *et al.*, 1990). The human *TPH-1* gene was found to localize to chromosome 11 by somatic cell hybrid mapping (Ledley *et al.*, 1987), and specifically to chromosome 11p15.3-p14 by *in situ* hybridization (Craig *et al.*, 1991). The isolation and organization of the human *TPH-1* gene showed that it spans 29 kb and contains 11 exons (Boularand *et al.*, 1995a). Additionally, four mRNA species were observed in pineal gland and in carcinoid tumor resulting from differential splicing of three intron-like regions and of three exons located in the 5'UTR of the gene (Boularand *et al.*, 1995a). Furthermore, alternative splicing at the 3' end of the cDNA sequence of the human gene generates two human *TPH-1* isoforms with different carboxy termini that are expressed in both brain and pineal gland. However, only the spliced mRNA species was detected in most brain regions, including brainstem, midbrain and cerebellum, whereas the non-spliced transcript expression was limited to only some brain regions (Wang *et al.*, 1998).

The 5'UTR of the rat *TPH-1* gene has revealed the presence of two promoter regions, with the proximal one exhibiting two 'CCAAT homologies' (Delort *et al.*, 1989). In the mouse the promoter region was suggested to be upstream from the transcription initiation site, where a CAAT and a TATA box were present 55 bp and 25 bp, respectively (Stoll and Goldman, 1991). However, the transcriptional regulation of the mouse *TPH-1* gene was further elucidated, revealing the proximal promoter between -77 and -46 nucleotides and an activator region between nucleotides -343 and -21 bp in P815-HTR mastocytoma cells (Reed *et al.*, 1995). Furthermore, the transcription factor NF-Y (also known as CP-1 and CBP, and which interacts with CCAAT boxes found in Y boxes) was found to bind to the GGCCAAT motif in the mouse *TPH-1* promoter and activates transcription (Reed *et al.*, 1995). In humans, a minimal promoter region was active in pinealocyte cultures and PC12 cells between -73 and -51 nucleotides that drove cAMP-dependent transcription. It has an inverted CCAAT box rather than a cAMP-responsive element (Boularand *et al.*, 1995b). An additional inverted CCAAT box and a GC-rich region in the optimal promoter (-252/+29) of the human *TPH-1* gene interacted with NF-Y and Sp1 binding proteins in the basal and cAMP-stimulated transcriptional activation in pinealocytes (Cote *et al.*, 2002). Interestingly, other studies have shown that the transcription factor CCAAT box binding factor (CBF)/nuclear factor-Y (NF-Y) activates the transcription of the human *TPH-1* gene (Teerawatanasuk and Carr, 1998), whereas CCAAT displacement protein (CDP/Cut) interacts with the negative regulatory element of the gene (Teerawatanasuk *et al.*, 1999).

There is evidence showing that the TGT haplotype of 3 SNPs (T-1607C, G-1066A, T-346G) within the 5' regulatory region of the *TPH-1* gene repressed transcriptional activity in human choriocarcinoma and colon adenocarcinoma cell lines; however, only the T-346G marker showed association with alcohol dependence in a Taiwanese group (Sun *et al.*, 2005).

### ***Tryptophan hydroxylase 2 gene (TPH-2)***

Gene targeting studies in mice led to the discovery of the second *TPH* gene, termed as *TPH-2*, with homologs of the gene additionally cloned and sequenced in humans and rats (Walther *et al.*, 2003). *TPH-1* and *TPH-2* show 71 percent amino acid identity in humans. In mice the *TPH-2* mRNA is primarily detected in the brain, whereas the *TPH-1* gene is expressed in the periphery, including the gut, pineal gland, spleen and thymus (Walther *et al.*, 2003; Cote *et al.*, 2003; Walther and Bader, 2003).

In rats, studies also revealed specific and high *TPH-2* mRNA expression in midbrain and brainstem raphe nuclei, with the *TPH-1* gene expression detected predominantly in the pineal gland (Patel *et al.*, 2004). In humans, *TPH-2* gene expression levels were highest in frontal cortex and thalamus followed by hypothalamus, lowest in the hippocampus and amygdala, and barely detectable in peripheral tissues (Zill *et al.*, 2004a). However, the first study demonstrated *TPH-1* and *TPH-2* mRNA expression in different regions of human *post-mortem* brain (Zill *et al.*, 2007). Interestingly, recent data from our group have revealed that mRNA expression of *TPH-1* in most human *post-mortem* brain regions is generally comparable or higher than that of *TPH-2* gene expression (Sugden *et al.*, 2009). These data confirm previous results where the *TPH-1* expression was higher than *TPH-2* in human cortex and thalamus and these differences were significant in hypothalamus and amygdala (Zill *et al.*, 2007). However, *TPH-1* gene expression levels were significantly higher than *TPH-2* mRNA expression in the striatum and cerebellum but not in the hippocampus, which showed higher *TPH-2* gene expression than *TPH-1* (Sugden *et al.*, 2009). This inconsistency could be related to factors such as the differing mean ages of samples analyzed in our study and that by Zill and colleagues (2007). Lately, a regulatory domain of 41 amino acids in the N terminus was found in *TPH-2* and not in *TPH-1*, which controls enzyme protein expression and phosphorylation of serine 19 (a protein kinase A consensus site) located in this region, resulting in increased *TPH-2* stability and enzyme activity in cell culture systems (Murphy *et al.*, 2008).

Several studies have identified functional polymorphisms in the *TPH-2* gene (reviewed in Zhang *et al.*, 2006). These include C1473G SNP, which reduced 5-HT levels in murine frontal cortex and striatum, indicating that *TPH-2* controls brain serotonin synthesis (Zhang *et al.*, 2004). Interestingly, a functional SNP G1463A which results in an amino acid change from arginine to histidine in the human *TPH-2* gene resulted in 80 percent loss of function in serotonin synthesis when expressed in PC12 cells, and is more frequent in unipolar depression than bipolar depression (Zhang *et al.*, 2005). A previous human study showed a significant association with an SNP and a haplotype of SNPs between exons 5 and 7 of the *TPH-2* gene with major depression (Zill *et al.*, 2004b). More recently, two marker SNPs located in exons 7 and 9 showed differential expression of *TPH-2* mRNA levels in the pons region of human *post-mortem* brain. These SNPs are closely linked to *TPH-2* SNPs previously found to be associated with major depression and suicide (Lim *et al.*, 2007). Additionally, a novel short isoform of the *TPH-2* gene was identified with a truncated catalytic domain

which was expressed in human brainstem, prefrontal cortex, hippocampus and amygdala, and an SNP (A22879G) in exon 6 of this short isoform was associated with major depression (Haghighi *et al.*, 2008). Nonetheless, higher levels of *TPH-2* mRNA were found in the dorsolateral prefrontal cortex in *post-mortem* brains from patients with bipolar disorder, suggesting a potential role of the gene in the pathophysiology of this disorder (De Luca *et al.*, 2005). Studies in rhesus monkey revealed two nonsynonymous SNPs in a haplotype with significantly higher expression of the *TPH-2* gene and protein, higher 5-HT production and lower mRNA stability than the wild type when stably expressed in PC12 and HEK293 cells (Chen and Miller, 2008).

Recent studies have indicated that the core promoter region of the human *TPH-2* gene is localized between -107bp and +7bp and in the region of +8bp to +53bp in the 5'UTR negatively regulated gene expression at transcriptional and post-transcriptional levels (Chen *et al.*, 2008). However, fMRI studies demonstrate that an SNP (rs570625; G-703T) in the upstream regulatory region of the gene increases amygdala reactivity to emotional stimuli (Brown *et al.*, 2005; Canli *et al.*, 2005) and to angry faces in patients with social anxiety disorder in a recent positron emission tomography (PET) study (Furmark *et al.*, 2009). Another T-473A (rs11178997) polymorphism in the 5' regulatory region of the *TPH-2* gene was associated with unipolar and bipolar depression (Van Den Bogaert *et al.*, 2006), significantly reduced transcriptional activity in primary serotonergic neurons from rat raphe nuclei and in human small lung carcinoma SHP-77 cells, and reduced binding to the transcription factor POU3F2 (also known as Brn2, n-Oct-3) to the A-allele (Scheuch *et al.*, 2007). POU domain factors are transcriptional regulators characterized by a highly conserved unique bipartite DNA-binding domain referred to as the POU domain. The acronym POU (pronounced 'pow') is derived from the names of three mammalian transcription factors: the pituitary-specific Pit-1, the octamer-binding proteins Oct-1 and Oct-2, and the neural Unc-86 from *Caenorhabditis elegans*. Another recent study examined the functional effects of the haplotype of the two polymorphisms (G-703T and T-473A) in the 5'-flanking region of the human *TPH-2* gene mentioned above together with a third common variant A90G in the 5'UTR of the gene (Chen *et al.*, 2008). In both RN46A (a serotonergic cell line derived from embryonic day 13 rat medullary raphe nuclei) and HEK293 cells it was demonstrated that the haplotype (G-703T, T-473A and A90G) resulted in reduced transcriptional activity, and that all three polymorphisms potentially alter DNA-protein interactions (Chen *et al.*, 2008). Interestingly, further investigations on the regulation of the gene in mouse were reported where a novel

NRSE (neuron restrictive silencing element) motif interacts with the transcription factor REST/NRSF (RE-1 silencer of transcription/neuron restrictive silencer factor in C6 glioma cells) (Patel *et al.*, 2007). Finally, studies in rhesus monkeys demonstrated that 3'UTR polymorphisms and haplotypes modulate HPA axis function by altering the expression levels of the gene (Chen *et al.*, 2006).

### Serotonin transporter gene (*SERT*, *5-HTT*, *SLC6A4*)

The *SERT* gene is located on chromosome 17, and contains 14 exons spanning 31 kb (Lesch *et al.*, 1994). Its organization bears striking similarity to that of other members of the Na<sup>+</sup>/Cl<sup>-</sup> neurotransmitter transporter family. Bradely and Blakely (1997) used 5' RACE to examine the pattern of transcripts and discovered alternative first exons (1A and 1B). Transcripts containing either one or other of these were identified in the human placental JAR cell line, in which interleukin-1 beta is a potent regulator of the *SERT* locus. Exon 1B is not preceded by a TATA element, as suggested for the promoter upstream of exon 1A. Exon 2 contains the translation initiation site. The wide range of transcripts sizes between 2 and 4 kb is partly explained by differential splicing, but also probably by the presence of two rare polyadenylation sites at the 3' end of the gene (5'-AATGAA-3' and 5'-AATATA-3') and of a third polyadenylation signal similar to that found in rat and mouse *SERT* genes, thereby providing opportunity for variable polyadenylation (see Bradely and Blakely, 1997; Battersby *et al.*, 1999).

The most studied polymorphism of the *5-HTT* locus is located 1 kb upstream from the transcription start site and was identified initially by Heils *et al.* (1995, 1996). The basic polymorphism (*5-HTTLPR*) comprises a 44-bp insertion or deletion, creating either a 'long' 16-repeat allele or a 'short' 14-repeat allele, together with other low-frequency alleles including 15, 18, 19, 20 and 22 repeats, and there are various additional SNPs distinguishing some repeats (Delbruck *et al.*, 1997; Kunugi *et al.*, 1997; Michaelovsky *et al.*, 1999; Nakamura *et al.*, 2000). Flattem and Blakely (2000) noted a potential unstable sequence of 381 bp located between the *5-HTTLPR* and the transcription start site which is present in some but not other cloned sequences. They speculate that this may be detected in some individuals.

Classic studies have suggested that the short allele is associated with both lower transcriptional potential and anxiety-related personality traits, particularly neuroticism and affective disorders (reviewed in D'Souza and Craig, 2008). This review also summarizes the functional studies of the polymorphism in mammalian cell lines, lymphocytes, blood platelets and brain, and thus

these are only briefly described here. The short variant of the *5-HTTLPR* had lower transcriptional activity, *5-HTT* expression and 5-HT uptake than the long variant in human placental choriocarcinoma (JAR) and peripheral lymphoblast cells (Heils *et al.*, 1996; Lesch *et al.*, 1996). This pattern has also been supported in part by neuro-imaging studies (see D'Souza and Craig, 2008). A variety of subsequent investigations have generally supported the higher transcriptional levels observed for the long allele, but the picture is complicated by the existence of SNPs both within the promoter repeats and elsewhere in the gene (see Nakamura *et al.*, 2000; Hu *et al.*, 2006; Martin *et al.*, 2007). Very recent studies have investigated associations based on haplotypes which combine variants providing information throughout the locus and potentially tracking additional functional variants (see Mrazek *et al.*, 2008).

The importance of the *5-HTTLPR* region is highlighted in a study of gene-by-environment interaction ( $G \times E$ ), which showed that individuals having one or two copies of the short allele of the *5-HTTLPR* polymorphism exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events than individuals homozygous for the long allele (Caspi *et al.*, 2003). A second  $G \times E$  study demonstrated that individuals with adolescent depression had a significant interaction between environmental risk and short alleles of *5-HTTLPR*, with the effect being observed in females only (Eley *et al.*, 2004). Additionally, independent groups have replicated the main findings of Caspi *et al.* (2003) (Kaufman *et al.*, 2004; Kendler *et al.*, 2005; Wilhelm *et al.*, 2006), although Gillespie *et al.* (2005) were unable to reproduce the gene by environment effect. In addition, Chorbov and colleagues (2007) described a  $G \times E$  trauma interaction in the predisposition to major depressive disorder observed with high expression (long alleles – classified according to Hu *et al.*, 2006). Further replication is provided by studies on the Spanish PREDICT cohort, where both the SS homozygous genotype and increased life-threatening events enhanced the probability of depression, particularly after adjusting for gender age and family history of psychological problems (Cervilla *et al.*, 2007). Providing a possible insight into the mechanisms involved, it was found that girls homozygous for the S allele were apparently more reactive to stress measured by cortisol production than were those with an L allele (Gotlib *et al.*, 2008).

A sex-specific effect has been reported in which, for females, the S allele, combined with care-giving stress or low childhood socioeconomic status, was associated with higher depression scores as compared to participants in the non-stressor group and those with the long (L) allele. In contrast, for males, the L allele, combined with

a stressor, was associated with higher depression scores as compared to those in the non-stressor group and those with the S allele (Brummett *et al.*, 2008).

Detailed examination of markers throughout the gene, including four haplotype tagging SNPs (rs2020942, rs140700, rs3798908 and rs1042173), found that, in addition to influences of the *5-HTTLPR*, the central region of the locus was also implicated in explanations of  $G \times G \times E$  interactions for mood (Lazary *et al.*, 2008). Overall, the original observations of Caspi *et al.* (2003) appear to have been replicated robustly. Most recently, other associated phenotypes also appear to fit the pattern of adversity interactions with genotype; specifically, S/S individuals with higher levels of maltreatment had significantly higher levels of anxiety susceptibility (although not neuroticism) than subjects in other groups (Stein *et al.*, 2008).

As reviewed previously (D'Souza and Craig, 2008), in addition to the promoter repeat, another example of a functional VNTR polymorphism in the serotonin transporter gene is located in intron 2 (termed as Stin2 VNTR). It comprises 9, 10 or 12 copies of a 16/17-bp element. Functional studies in differentiating embryonic stem cells *in vitro* and in transgenic mice *in vivo* revealed the Stin2 VNTR acts as a transcriptional regulator in an allele-dependent manner, with the 12-repeat allele demonstrating stronger enhancer activity than the 10-repeat allele. Additional investigations suggest that not only the number but also the primary structure of the repeats could affect the transcription of the gene (Lovejoy *et al.*, 2003). Furthermore, two transcription factors, YB-1 (Y box binding protein 1) and CTCF (CCTC-binding factor) were found to be responsible for the regulation of the Stin2 VNTR function as a transcriptional regulatory domain (Klenova *et al.*, 2004).

Indeed, given the possibility that the *5-HTT* locus may be a target for the therapeutic effects of lithium (LiCl) in treatment of depression, Roberts *et al.* (2007) demonstrated that LiCl modified the levels of CTCF and YB-1 mRNA and protein and that both CTCF and YB-1 showed differential binding to the allelic variants of the Stin2 VNTR and may result in alterations of *SLC6A4* expression. The complexity of the interactions is further increased by the potential interaction of LiCl with the *5-HTTLPR*, which contains domains potentially capable of interaction with CTCF.

There have been reported associations of Stin2 VNTR with behavioral disorders, including strong evidence for increased frequency of allele 12 of the VNTR with subjects having bipolar disorder (Collier *et al.*, 1996). Additionally, significant differences exist between patients with unipolar disorder and controls in the proportion of individuals having allele 9 (Battersby *et al.*, 1996; Ogilvie

*et al.*, 1996). Moreover, an increased frequency of the 10 allele of this intron polymorphism together with the long allele of the promoter polymorphism of the serotonin transporter gene was observed in a suicide cohort having Slavic ethnicity (Hranilovic *et al.*, 2003). Furthermore, an independent report showed that the combined genotype at both *5-HTTLPR* and Stin2 locus ('low expressing' genotypes containing at least one short allele) lowered *5HTT* gene expression levels in lymphoblastoid cell lines from subjects having schizophrenia or schizoaffective disorder using a real-time PCR method (Hranilovic *et al.*, 2004).

Finally, epigenetic modification may provide an additional feature capable of modifying genotype effects in regulating *SERT* expression in a sex-specific manner. A study on lymphoblastoid lines indicated that the CpG island overlapping the 5' region of the locus is more heavily methylated in females, resulting in reduced transcription (Philibert *et al.*, 2007, 2008)

### Brain-derived neurotrophic factor gene (*BDNF*)

BDNF (brain-derived neurotrophic factor) has been shown to modulate serotonin transporter function in lymphoblast cells (Mossner *et al.*, 2000), and variants in this locus are highly relevant to the functionality of the monoamine pathways. The gene is located on 11p14 and codes for the precursor peptide (proBDNF) that is cleaved proteolytically to form the mature protein. BDNF is known to modulate hippocampal plasticity and hippocampal-dependent memory in cell models and animals. It plays an important role in regulating transmitter systems, neuronal survival and regeneration, and consequently is a key candidate for implication in behavioral disorders. The *BDNF* locus was originally reported to have a minimum of five 5' non-coding exons (Aoyama *et al.*, 2001; Marini *et al.*, 2004); however, nine transcripts have been identified which differ in their use of alternative promoters, alternative splice donor and acceptor sites, and alternative polyadenylation sites (Liu *et al.*, 2006). Most transcripts encode proBDNF; however, two transcripts contain additional in-frame methionines that may result in proteins with longer N termini. These authors also identified non-coding RNAs transcribed from a gene that overlaps with BDNF on the opposite strand (BDNFOS) (Pruunsild *et al.*, 2007). In a detailed dissection of the *BDNF* locus, Pruunsild *et al.* (2007) show that the gene has 11 exons and 9 functional promoters which operate in a tissue- and brain-region-specific manner. A significant role may also be attributed to a range of differentially spliced non-coding antisense transcripts which are produced from an anti-BDNF locus (BDNFOS), which form double-stranded duplicates in the brain *in vivo*, suggesting an important role for anti-BDNF

in regulating BDNF expression (Pruunsild *et al.*, 2007). Furthermore, they identified non-coding natural antisense RNAs that display complex splicing and expression patterns which are transcribed from the BDNF gene locus. A total of at least 34 different transcripts can be produced, although their relative physiological significance remains to be established. Most recently, Baj and Tongiorgi (2009) have investigated the *BDNF* transcripts responsible for cell survival of neuroblastoma cell lines SH-SY-5Y and SK-N-BE in a model system employing small inhibitor (si) RNAs. The evidence suggests that mRNA isoforms coupling exons 4 or 6 or 9a to the coding exon 9 are necessary for survival.

Various *trans* acting factors may serve to modulate the expression of the locus, including the DNA binding protein Pitx3, a homeodomain transcription factor required for the development of midbrain dopaminergic neurons (Peng *et al.*, 2007). Additional evidence suggests that estrogen may also be important in the regulation of the *BDNF* gene (Scharfman and MacLusky, 2006; Sohrabji and Lewis, 2006). Also of interest is that the *BDNF* locus is one of the few well-defined targets of the methyl-binding protein *MECP2* gene, mutations in which are responsible for Rett syndrome (Chen *et al.*, 2003). More recently, microRNA, miR-30a-5p, has been found to act as a post-transcriptional inhibitor of BDNF in the prefrontal cortex (Mellios *et al.*, 2008).

A SNP has been identified in the 5' pro-BDNF sequence at nucleotide 196 (G/A), producing an amino acid substitution (valine to methionine) at codon 66 (Val66Met). Genetic association studies and functional studies of this particular polymorphism and other variants in the gene have been reviewed recently and thus are only briefly summarized here (D'Souza and Craig, 2008). The Met allele has been found to be associated with bipolar disorder in adults (Neves-Pereira *et al.*, 2002; Sklar *et al.*, 2002; Lohoff *et al.*, 2005), although a very large study showed significant association only with a rapidly-cycling subset (Green *et al.*, 2006). Several studies have examined the functional impact of this polymorphism, revealing that Met allele exhibited abnormal intracellular trafficking, impaired secretion and storage of BDNF protein compared with the Val allele in neuronal cells (Egan *et al.*, 2003; Chen *et al.*, 2004) and with diminished hippocampal engagement using BOLD (blood oxygen level-dependent) fMRI in comparison with Val homozygotes (Hariri *et al.*, 2003).

Investigation of a complex structure embracing three types of dinucleotide repeats which is located about 1.0kb from the translation initiation site has been determined. Insertion/deletion and nucleotide substitutions within the repeat motifs resulted in the identification of 23 alleles, and this BDNF-linked complex polymorphic

region is known as *BDNF-LCPR*. One major allele was associated with bipolar disorder, and this allele showed reduced transcription in a luciferase coupled assay (Okada *et al.*, 2006). A synonymous second SNP (rs988748) has been described, but there are no significant functional or disease associations reported. Interestingly, the picture emerges of the *BDNF* locus with excellent credentials as a candidate gene in behavioral disorders, but also of one whose complexity of regulation and response to external and *trans* acting factors complicate simplistic interpretations.

### Monoamine oxidase genes (*MAO*)

The monoamine oxidases A and B are the products of two abutting X-linked genes, and play an important role in the metabolism of biogenic amines in the central nervous system and in the periphery. Monoamine oxidases are oxygen oxidoreductase (deaminating) flavin-containing enzymes, and the two forms of the enzyme, MAO-A and MAO-B, differ in specificity for substrates, sensitivity to inhibitors, tissue distribution and immunological properties. In general, MAO-A preferentially oxidizes the biogenic amines such as serotonin, norepinephrine and epinephrine, whereas MAO-B catalyzes phenylethylamine and benzylamine. However, dopamine, tyramine and tryptamine are common substrates for both forms of the enzyme.

The cDNA nucleotide sequences of MAO-A and MAO-B genes were determined from human liver (Bach *et al.*, 1988). Studies on the genomic organization of the two loci indicate that they have considerable homology (73 percent at the amino acid level), and each comprises 15 exons with the genes arranged in a tail-to-tail configuration separated by about 40–45 kb (Chen *et al.*, 1991; Grimsby *et al.*, 1991). Furthermore, these studies showed that exon 12, which codes for the covalent FAD-binding site, is highly conserved (about 92 percent peptide identity) in both genes. The human MAO-A and MAO-B genes span 100kb, and the exon/intron boundaries in each gene occur at homologous positions in the protein sequence, suggesting they originated by gene duplication (Grimsby *et al.*, 1991). The human MAO-A and MAO-B genes were assigned to the X chromosome using rodent–human hybrid somatic cell lines (Pintar *et al.*, 1981; Kochersperger *et al.*, 1986) and specifically mapped to Xp11.23-11.4 by *in situ* hybridization (Ozelius *et al.*, 1988; Lan *et al.*, 1989; Levy *et al.*, 1989).

MAO-A is expressed in the outer mitochondrial membrane of specific cells in various brain and peripheral tissues. In human liver MAO-A transcript is 5 kb in length;

however, in small intestine and placenta an additional 2-kb mRNA species is present resulting from alternative polyadenylation sites (Grimsby *et al.*, 1990; Chen *et al.*, 1991). *MAO-B* transcript is 3 kb in human liver and is also expressed widely, including in the brain, and the enzyme is also found in platelets. The highest expression of *MAO-A* and *MAO-B* genes was found in the frontal cortex and locus coeruleus brain regions (Grimsby *et al.*, 1990).

A detailed investigation employing transfection and sequencing techniques revealed maximal promoter-like function. This was observed in conserved high CpG regions directly flanking the transcriptional start sites. Additional regulatory sites involving direct repeats at approximately 1.3 kb and 0.2 kb for the A and B loci respectively were noted (Zhu *et al.*, 1992). Although additional upstream initiation sites have been described, Denney *et al.* (1994) observed that most transcripts for *MAO-A* initiate between -30 and -40, with minor transcription initiating at -95 and -136. Unlike the *MAO-B* promoter, the *MAOA* promoter region of two 90-bp repeats lacks a TATA box and CACCC element; however, the core promoter regions of both genes consist of two sets of overlapping Sp1 sites (Shih *et al.*, 1993, 1994). The significant differences in their promoter regions are presumed to explain the tissue- and cell-specific expression profiles of the two forms. Upstream repeating units were found to downregulate the promoter region of the human *MAO-A* gene independent of an initiator-like sequence in human glioma (1242 MG) and HeLa cells. Several transcription factors are known to regulate the human *MAO-A* promoter and include Sp1 (Zhu *et al.*, 1994), whereas R1 (RAM2/CDCA7L/JPO2) inhibits promoter and enzymatic activity in human neuroblastoma and glioblastoma cells (Chen *et al.*, 2005; Ou *et al.*, 2006). Comprehensive studies show that activation of the *MAO-A* promoter region by glucocorticoid and androgen is regulated differently by R1 and Sp1 (Ou *et al.*, 2006). The human *MAO-B* promoter region interacts with Sp1 and Sp3 (Wong *et al.*, 2001).

There is strong evidence that *MAO-A* plays an important role in human and animal behavior, and regulation of the *MAO-A* locus by an upstream VNTR has been the focus of many disease-association studies. These findings have recently been reviewed (D'Souza and Craig, 2008), and therefore only key results will be highlighted here, with a focus on updated information. First, a nonsense mutation (in exon 8 of the gene that leads to the production of a truncated, non-functional, protein) was found to be associated with impulsive aggressive behavior in affected males in a single large family studied in Holland (Brunner *et al.*, 1993). Increased aggression also characterized adult male transgenic mice having a deletion in the *MAO-A* gene (Cases *et al.*, 1995). A VNTR

polymorphism is located 1.2 kb upstream of the coding region and consists of a 30-bp repeated sequence present in 3, 3.5, 4 or 5 copies with functional effects determined in human neuroblastoma and placental choriocarcinoma cell lines and also in *post-mortem* brain tissue (Sabol *et al.*, 1998; Deckert *et al.*, 1999; Balciuniene *et al.*, 2002).

Strong evidence, however, has been observed regarding the effects of the environment on the behavioral outcomes of different *MAO-A* promoter variants. In a gene-environment study, maltreated children were less likely to develop antisocial problems when they had the genotype in the 5' regulatory region that confers high levels of *MAO-A* expression (Caspi *et al.*, 2002). Subsequent studies attempted to replicate these findings, demonstrating a significant role for *MAOA* variants interacting with stressful upbringing in predisposing to ASB (antisocial behavior) (Foley *et al.*, 2004; Nilsson *et al.*, 2006; Widom and Brzustowicz, 2006) and as predictors of destructive behavior during male adolescent alcohol consumption (Nilsson *et al.*, 2007).

There are far fewer data relating to *MAO-A* functional variants and females, possibly resulting from the complication of its X-localization and the perceived potential confound of its undetermined level of escape from inactivation; however, in a recent study, a gene by environment interaction was observed suggesting that girls with high-rather than low-activity alleles may be at increased risk of criminal behavior in the presence of psychosocial risk (Sjoberg *et al.*, 2007). A study of allelic expression patterns of *MAO-A* in brain has concluded that there was no evidence for skewing in normal individuals (Pinsonneault *et al.*, 2006). The interrelationship between the functional variants in the *MAO-A* promoter and HPA axis stress response that may underpin the G  $\times$  E interaction has been recently reviewed (Craig, 2007).

Finally, the link between genotype and brain has been approached at the neuroimaging level. Neuroimaging studies by Meyer-Lindenberg *et al.* (2006) indicated that low-activity genotype in healthy males predicted pronounced reductions in volume that include virtually the entire cingulate gyrus and bilateral amygdalae. There were also genotype-dependent differences in amygdala activation during emotional arousal. Passamonti *et al.* (2006) employed blood oxygenation level-dependent (BOLD) fMRI to examine a genotype effect on a response inhibition task in healthy males. A greater response was observed in the Brodman's area in high-activity genotypes, whereas a greater response was observed in the right superior parietal cortex and bilateral extrastriate cortex in low-activity genotypes. In a first attempt to correlate brain *MAO-A* activity with genotype measured by positron emission tomography with the labeled ligand  $^{11}\text{C}$ chloglyline, no significant differences in *MAO-A*

activity were observed between the high- and low-activity genotypes (although a trend for higher activity was observed in the predicted direction for the visual cortex) (Fowler *et al.*, 2007). In a subsequent publication by the same group (Alia-Klein *et al.*, 2008), it was shown that lower brain MAO-A activity in cortical and subcortical brain regions correlated with higher self-reported trait aggression (observed in both high and low genotype groups). It seems, therefore, that genotype–brain and genotype–behavior relationships may be developmentally complex.

Other detailed functional, structural and connectivity investigations have suggested that the low-activity MAO-A allele adversely prejudices information processing within the amygdala, rostral cingulate and medial prefrontal cortex. High serotonin levels resulting from lower rates of metabolism may labilize such circuits required in social and emotional adjustment. This in turn may predicate an amplification of adverse early life experiences in genotype-vulnerable individuals (Buckholtz and Meyer-Lindenberg, 2008).

## Conclusions

The serotonergic gene system consists of several genes, including a number of receptor subtypes with different pharmacological/signaling properties, anabolic and catabolic enzymes and the high-affinity sodium-chloride dependent transporter which is regulated by a neurotrophic factor. The genomic organization of these genes is diverse, with a complex transcriptional regulation, and is summarized in Table 1. Furthermore, RNA splicing and post-transcriptional modifications such as RNA editing within some serotonergic genes generates a mechanism whereby single genes produce multiple proteins with different structures and functions. The plethora of gene products is important in the physiological and behavioral effects of serotonin, not only in the brain but throughout the whole organism, and they serve as targets for drug development/therapeutic strategies. Moreover, the functional polymorphisms in genes within this system have provided an understanding of the plausible molecular mechanisms underlying neurobehavioral disorders.

## Acknowledgements

We would like to acknowledge the Medical Research Council (MRC), which supported research on a component grant entitled ‘Functional analysis of mutations in genes of monoamine neurotransmitters metabolism that are associated with behavioral disorders’ (Grant

**Table 1** Summary of gene structure and regulation of the serotonergic genes as reviewed in the text

	Gene organization (coding and 5' regulatory region)	Features in promoter region	Regulation by transcription factors
5-HT <sub>1A</sub>	Intronless (single exon)	No TATA box and GC rich (human); TATA box (rat)	MAZ (Pur-1, Zif87), Sp1, Deaf-1, Freud-1, corticosteroids
5HT <sub>1B/1D/1E/1F</sub>	Intronless (single exon)	—	—
5-HT <sub>2A</sub>	3 exons separated by 2 introns	No TATA or CAAT boxes	Sp1, PEA3, E-box proteins
5-HT <sub>2B</sub>	3 exons separated by 2 introns	—	—
5-HT <sub>2C</sub>	4 exons separated by 3 introns	No TATA box	—
5-HT <sub>3A</sub>	9 exons separated by 8 introns	—	—
5-HT <sub>3B</sub>	—	Two promoter regions. No TATA or CpG islands	—
5-HT <sub>4</sub>	10 exons, 1 untranslated exon	No TATA or CAAT boxes	Nkx2.5
5-HT <sub>5</sub>	2 exons separated by 1 intron	—	—
5-HT <sub>6</sub>	3 exons separated by 2 introns	—	—
5-HT <sub>7</sub>	5 exons separated by 3 introns	No TATA or CAAT boxes, GC rich	Sp1, Sp3
TPH-1	11 exons	Two promoters in rat and in mouse TATA and CAAT boxes present	NF-Y, Sp1, CBF/NF-Y, CDP/Cut
TPH-2	Refer to cited articles	1 promoter region	POU3F2 (Brn2), REST/NRSF
5-HTT	14 exons		YB-1, CTCF
BDNF	11 exons	9 promoter regions	Pitx3, oestrogen
MAOA	15 exons	No TATA or CACC boxes and GC rich	Sp1, R1

# The Neuroanatomy of the Serotonergic System

Jean-Pierre Hornung\*

*Département de Biologie Cellulaire et de Morphologie, Faculty of Biology and Medicine, University of Lausanne,  
Rue du Bugnon 9, 1005, Lausanne, Switzerland*

**Abstract:** Neurons using serotonin as a neurotransmitter in the central nervous system are restricted to the brainstem, centered on the midline raphe nuclei, extending into the subnuclei of the lateral reticular formation. These neurons divide into two populations. A rostral group resides in the midbrain and rostral pons (caudal linear, dorsal and median raphe nuclei), with a major projection targeted to the forebrain. A caudal group located in the caudal pons and the medulla (raphe magnus, obscurus and pallidus nuclei, lateral medullary reticular formation) has a major projection targeted to the spinal cord. Both groups have projections to the brainstem. Subnuclei of the serotonergic system have distinctive afferent and efferent connections, with some entities more specifically linked to the sensory, motor or limbic systems. Serotonergic neurons segregate, based on their axonal morphology, into neurons with large varicose or small varicose axons, the latter being selectively sensitive to neurotoxins derived from amphetamines. This is the basis for a dual serotonergic projection system, which partially overlaps in certain structures such as the cerebral cortex. Small varicose axons form wide axonal arborization of various densities of synaptic boutons, sustaining a system of volume transmission. Large varicose axons form pericellular arrays of synaptic terminals surrounding the soma and proximal dendrites of selected neurons. Median raphe, raphe obscurus and raphe pallidus nuclei are the sources for serotonergic neurons with large varicose axons. As one of the diffuse aminergic systems of the brain, the serotonergic system segregates clearly into different entities, with subnuclei holding their own efferent and afferent connections, serotonergic neurons having different axonal morphologies and synaptic connections, and, finally, numerous serotonin receptor subtypes having different expression patterns across the brain.

**Keywords:** raphe nuclei, rostral group, caudal group, large varicose axons, small varicose axons.

## Introduction

Serotonin was first isolated from enterochromaffin cells (and originally named 'enteramine' by Erspamer and Viali in 1937, and later identified as serotonin (Erspamer and Asero, 1952)). Serotonin synthesis involves the specific rate-limiting enzyme tryptophan hydroxylase (TPH), encoded in two distinct genes: TPH-1 in peripheral tissue, and TPH-2 in the central nervous system (Walther *et al.*, 2003). Serotonin-synthesizing neurons of the CNS express additional proteins for the regulation of serotonin neurotransmission, in particular the serotonin transporter (SERT) and the vesicular monoamine transporter 2 (VMAT2), which are essential for the sequestration and vesicular release of serotonin (Gaspar *et al.*, 2003; Murphy and Lesch, 2008). Although brain serotonin was detected biochemically (Twarog and Page, 1953; Bogdanski *et al.*, 1956) and its effects on behavior and

mood hypothesized (Woolley and Shaw, 1954) during the 1950s, it was only in the 1960s that serotonergic neurons could be directly visualized for the first time using the histochemical fluorescent method (Dahlström and Fuxe, 1964). More accurate and detailed morphological analysis of the serotonergic neurons was later achieved using immunocytochemical techniques, with antibodies against TPH (Pickel *et al.*, 1977), serotonin itself (Steinbusch, 1981) and the serotonin transporter (Ovalle *et al.*, 1995; Sur *et al.*, 1996; Zhou *et al.*, 1996).

The serotonin-containing neurons were characterized by a distribution restricted to the brainstem, and particularly to clusters of cells named B1 to B9 (Dahlström and Fuxe, 1964) which were mainly restricted to the midline raphe nuclei. In total, a few tens (in rodents) to a few hundreds (in human) of thousands of serotonergic neurons, segregated into a rostral and a caudal group, give rise to a dense axonal innervation to nearly all divisions of the CNS. This feature, shared with the other central amine systems, led to the concept of a volume transmission

\*E-mail: jean-pierre.hornung@unil.ch

mechanism modulating the function of specific local circuits across systems (Fuxe *et al.*, 2007). However, parallel studies using various tracing and mapping methods outlined subdivisions and specific connection between groups of serotonergic neurons (see subsequent sections of this chapter). The specificity of connections within the serotonergic system relies on several parameters: (1) the subdivision of raphe nuclei into spatially and morphologically distinct neuronal clusters; (2) a contrasting density of the serotonergic axonal arborizations between cytoarchitectonic divisions of the brain; (3) a distinct axonal morphology and distribution originating from different raphe nuclei; and (4) a large repertoire of serotonin receptors with specific cellular and regional pattern of expression (see Chapter 1.6).

The lineage of the serotonin-synthesizing neurons associates the coordination of several transcription factors which specify their location caudal to the midbrain–hindbrain organizer in two cellular clusters in rhombomers 1–3 and 5–7 (Alenina *et al.*, 2006). The original anatomical subdivision of the serotonergic nuclei is well supported by the current molecular characterization of these neurons. Among them, Pet-1 is a serotonin specific transcription factor expressed in embryonic and adult serotonergic neurons (Hendricks *et al.*, 1999). The ongoing studies on the contribution of each of these factors to the establishment of the serotonergic system will further consolidate our knowledge of its functional organization (see Chapter 1.2).

Finally, it should be recognized that the serotonergic system is generated early during embryogenesis, and that serotonin transmission sustained by early serotonergic neurons, and by non-serotonergic neurons expressing transiently protein-regulating serotonin transmission (transporters, receptors), contributes to proper brain development (see Chapter 3.1).

### **Divisions of the raphe and associated serotonin-containing nuclei**

Using the histochemical fluorescent method, the distribution of serotonergic neurons was first described as nine groups in the brainstem, labeled caudally to rostrally as B1 to B9 (Dahlström and Fuxe, 1964). Since a large proportion of serotonin-containing neurons reside at the midline, there has been an extension of the use of the name *raphe nuclei* to refer to the source of serotonergic innervation of the brain. The raphe nuclei belong to the midline division of the reticular formation of the brainstem, extending from the midbrain rostrally to the decussation of the pyramidal tract caudally (Brodal, 1981). Except for the dorsal raphe nucleus, which is located

in the ventral periaqueductal gray, the raphe nuclei are positioned ventral to the medial longitudinal fasciculus. Histofluorescence and immunocytochemical studies in various mammalian species have established that most serotonin-containing neurons are located in the raphe nuclei, with a population extending laterally into the reticular formation. The higher proportion of serotonergic neurons positioned in the mesopontic reticular formation is a characteristic feature of the primate brain (Nobin and Björklund, 1973; Hubbard and Di Carlo, 1974; Schofield and Everitt, 1981; Schofield and Dixon, 1982; Felten and Sladek, 1983; Azmitia *et al.*, 1986; Takahashi *et al.*, 1986; Hornung and Fritschy, 1988).

The cell density and the cytoarchitectonic boundaries of the raphe nuclei vary, the dorsal raphe (DR) nucleus having the sharpest limits, while delineation of the caudal raphe nuclei is poor. The proportion of serotonin-containing neurons in a given cytoarchitectonic subdivision varies from between 80 and 100 percent in regions of the dorsal raphe, to 10 percent in the lateral reticular formation. The raphe nuclei and the serotonergic system of common laboratory animals have been described in detail elsewhere (Jacobowitz and MacLean, 1978; Wiklund *et al.*, 1981; Pecci-Saavadra *et al.*, 1983; Steinbusch *et al.*, 1983; Jacobs *et al.*, 1984; Azmitia *et al.*, 1986; Hornung and Fritschy, 1988; Törk, 1990; Bjarkam *et al.*, 1997; Léger *et al.*, 1998; VanderHorst and Ulfhake, 2006).

This chapter describes systematically the cyto- and chemoarchitecture of the raphe nuclei along the rostro-caudal axis of the brainstem, focusing on the median (in the raphe nuclei) and lateral (in the lateral reticular formation) distribution of serotonergic neurons. The following section describes the connectivity of the raphe nuclei.

### ***The rostral group***

Three raphe nuclei constitute the rostral serotonergic group extending from the caudal mesencephalon to the mid pons – the caudal linear nucleus (CLi), the DR, and the median raphe nucleus (MnR) – as well as a large population of serotonergic neurons in the paramedian and lateral mesopontic reticular formation, mostly associated with the median nucleus.

### ***Caudal linear nucleus***

The most rostral population of serotonergic neurons is located in the caudal mesencephalon. It represents the rostral population of the B8 group (Dahlström and Fuxe, 1964). The CLi belongs to the ventral mesencephalic tegmentum (Halliday and Törk, 1986). It is located at the midline, surrounded ventrally by the interpeduncular

nucleus and laterally on both sides by the red nuclei. Posteriorly, it is adjacent to the superior cerebellar peduncle decussation. Dorsally, at the level of the medial longitudinal fasciculi, CLi merges with the rostral-most division of the dorsal raphe at the level of the interfascicular division (see below). The serotonergic neurons of the CLi have an elongated dendritic arborization, with its main axis oriented in the rostro-caudal direction, parallel to the midline plane. In the primate brain there is an additional population of serotonergic neurons in the rostral division of the interpeduncular nucleus, with neurons displaying a distinctive multipolar dendritic morphology (Azmitia *et al.*, 1986; Hornung and Fritschy, 1988; Törk and Hornung, 1990).

Besides serotonergic neurons, the heterogeneous population of CLi neurons includes tyrosin hydroxylase (TH)-immunoreactive dopaminergic neurons, and substance P (SP)-containing neurons (Halliday *et al.*, 1990).

#### *Dorsal raphe nucleus*

The DR is the largest collection of serotonergic neurons, counting for about one third of all serotonergic neurons of the brain. It represents the population of the B7 (rostral) and B6 (caudal) groups, divided in five subnuclei located between the mesencephalic aqueduct and the medial longitudinal fasciculus (Dahlström and Fuxe, 1964), while all the other serotonergic nuclei are located ventral to this tract. The dorsal raphe spreads in the anteroposterior axis between the oculomotor and the abducens nuclei, with the widest expansion at the level of the trochlear nucleus. The dorsal division of the dorsal raphe (DRD) abuts the aqueduct and splits the periaqueductal gray. It contains medium multipolar serotonergic neurons. At the pontomesencephalic transition, a population of large multipolar neurons in the ventrolateral division of the dorsal raphe (DRVl) spreads dorsally and laterally to the eye muscle motoneurons. Small multipolar serotonergic neurons are restricted to the midline in the ventral division of the dorsal raphe (DRV), between the nuclei of the ocular motoneurons. The ventral-most serotonergic neurons of the dorsal raphe lie in the intermediate division of the dorsal raphe (DRI) between the two parasagittal tracts of the medial longitudinal fasciculus, with elongated dendritic arborization parallel to the sagittal plane, and contiguous to the sagittal division of the median raphe located ventrally and to the CLi located rostrally. In the pons, the dorsal raphe extends in two parasagittal columns of serotonergic neurons, the caudal division of the dorsal raphe (DRD), made of small neurons with dendrites, often parallel to the floor of the overlying fourth ventricle.

All neurons of the DRI are serotonergic, and the proportion declines to 80 percent in the DRV and 60 percent

in all other subdivisions. Several neurotransmitters have been identified among the DR neurons. Very few GABA-containing neurons in the DR synthesize 5-HT (Wang and Nakai, 1993; Stamp and Semba, 1995; Charara and Parent, 1998). The distribution of SP and catecholamine is restricted to the rostral DR. There is a high proportion of large to medium-sized SP-immunoreactive neurons with morphologies similar to the serotonergic neurons, and it is estimated that up to 40 percent of 5-HT neurons express SP (Baker *et al.*, 1991a). There are only few catecholaminergic neurons, of variable morphologies, scattered in the rostral DR. There are also a few neurons containing the neuropeptides dynorphin, angiotensin and enkephalin (Björklund and Hökfelt, 1985; Björklund *et al.*, 1990; Okere and Waterhouse, 2006). In the rostral DR (B7), there are nitric oxide (NO) neurons detected by nitric oxide synthase (NOS) immunocytochemistry or NADPH-diaphorase histochemistry. NOS is present in 5-HT neurons of the midline dorsal and ventral division, while NOS and 5-HT are mostly found in distinct neuronal populations in the lateral division of the dorsal raphe (DRVl) (Léger *et al.*, 1998; Tagliaferro *et al.*, 2001; Okere and Waterhouse, 2006). In DRC, there is a dense and restricted population of neurotensin-containing neurons (Jennes *et al.*, 1982).

#### *Median raphe nucleus (MnR) and pontomesencephalic reticular formation*

##### *(a) The median raphe nucleus*

The median raphe nucleus (MnR, corresponding to the B8 and B5 groups) is made of a midline and a paramedian division. They extend from the caudal end of the decussation of the superior cerebellar peduncles rostrally, to the middle of the metencephalon, below the medial longitudinal fasciculus dorsally to the ventral border of the tegmentum. The midline group is contiguous dorsally with the DRI without clear segregation, and the neurons of the midline MnR have a similar elongated dendritic arborization parallel to the sagittal plane. There are two paramedian streams of neurons flanking the midline group, with medium-sized multipolar neurons (Törk, 1990).

##### *(b) The serotonergic neurons of the pontomesencephalic reticular formation*

In the pontomesencephalic region, numerous serotonergic neurons form two distinct clusters in the lateral reticular formation of the rostral half of the pons: one in the oral pontine nucleus (PnO), in the center of the brainstem, and the second more ventrally in the suprallemniscal nucleus (SuL). The number of serotonergic neurons in the lateral versus medial/midline reticular formation varies between species, being lower in rodents and high in the rabbit

(Bjarkam *et al.*, 1997) and primates (Azmitia *et al.*, 1986), approaching even numbers in the latter species (Baker *et al.*, 1991b). In the PnO, serotonergic neurons are large with radiating dendrites, while they are medium-sized with preferentially horizontally oriented dendrites in the suprallemniscal nucleus, parallel to the dorsal limit of the medial lemniscus (corresponding to the B9 group).

In total, the MnR and pontomesencephalic reticular formation contain the second largest group of serotonergic neurons, amounting to 20–25 percent of the total serotonergic population. In the MnR, about 80 percent of the neurons are serotonergic in the midline subdivision, a proportion reduced to 30 percent in the paramedian region and very low in the lateral reticular formation. In the MnR there are a small number of peptidergic neurons, containing SP (Baker *et al.*, 1991a), cholecystokinin (Schiffmann and Vanderhaeghen, 1991), dynorphin, enkephalin and neurotensin (Björklund and Hökfelt, 1985; Björklund *et al.*, 1990).

### *The caudal group*

The caudal serotonergic group extends from the caudal metencephalon to the decussation of the pyramidal tract, at the brainstem–spinal cord junction. Three raphe nuclei – the raphe magnus nucleus (RMg), the raphe obscurus nucleus (ROb) and the raphe pallidus nucleus (RPa) – as well as a large population of serotonergic neurons in the lateral medullary reticular formation constitute the caudal group, in continuation caudally with the lateral wings of the raphe magnus. There is a narrow serotonin-free transversal segment at the middle of the pons that separates the rostral and the caudal groups.

### *Raphe magnus nucleus*

The raphe magnus nucleus (RMg) is the rostral-most nucleus of this group centered at the junction between the pons and the medulla, at the level of the facial nucleus (corresponds to the B3 group). It is restricted to the midline, overlying the medial lemniscus. It is located in the ventral tegmentum, extending caudally up to the anterior limit of the inferior olive nucleus. At the caudal level, serotonergic neurons extend more laterally in continuity with a column of serotonergic neurons in the lateral reticular medullary formation (lateral paragigantocellularis nucleus). At the midline serotonergic neurons are mainly bipolar (parallel to the sagittal plane), while they are multipolar in the paramedian and lateral reticular formation (Törk and Hornung, 1990).

Substance P has been shown to co-localize in RMg serotonergic neurons, as well as thyrotropin-releasing hormones (Halliday *et al.*, 1988a; Rikard-Bell *et al.*,

1990; Poulat *et al.*, 1992; Wu *et al.*, 1993), as well as other neuropeptides such as enkephalin, somatostatin and cholecystokinin (Björklund and Hökfelt, 1985; Björklund *et al.*, 1990). A population of NPY-containing neurons has been described in the human RMg (Halliday *et al.*, 1988b).

### *Raphe obscurus nucleus*

The raphe obscurus nucleus (ROb) is a long stream of neurons along the midline, extending rostro-caudally from the level of the facial nucleus to the decussation of the pyramidal tract (corresponds to the B2 group). In the rostral medulla, ROb is located dorsally to the RMg. ROb serotonergic neurons are small to medium-sized, with dendrites oriented dorsoventrally. Numerous SP-IR neurons (Del Fiaccio *et al.*, 1984; Halliday *et al.*, 1988a; Rikard-Bell *et al.*, 1990), and scattered galanin-containing neurons (Blessing and Gai, 1997), have been described in the ROb.

### *Raphe pallidus nucleus*

The raphe pallidus nucleus (RPa) is the smallest raphe nucleus (corresponds to the B1 group). It is a narrow collection of cells along the midline at the dorsal edge of the pyramidal tract, flanked laterally by the inferior olivary nuclei, starting rostrally at the level of the caudal end of the RMg. Serotonergic neurons of the RPa are slender, elongated neurons with few dendritic processes oriented predominantly dorsoventrally (Loewy, 1981; Nakamura *et al.*, 2002).

### *Serotonergic neurons in the lateral medullary reticular formation*

Serotonergic neurons are in the lateral reticular formation at all levels of the medulla, in continuity rostrally with the lateral extensions of the RMg. This column of neurons shifts laterally, in the caudal direction, into the lateral paragigantocellular reticular nucleus (LPGi). Caudally, serotonergic neurons are situated close to the medullary surface (Chan-Palay, 1977; Steinbusch, 1981; Jacobs *et al.*, 1984; Azmitia *et al.*, 1986).

Neurons of the lateral reticular formation are multipolar, and those near the ventrolateral border of the medulla have a bipolar morphology. In this region, there are serotonergic and catecholaminergic neurons which constitute two separate populations (Halliday *et al.*, 1988c).

## **Connectivity**

The entire network of the serotonergic projection is readily visualized with immunocytochemical detection of tryptophan hydroxylase, serotonin or SERT, which

are abundant and selectively expressed by serotonergic neurons (Pickel *et al.*, 1977; Steinbusch, 1981; Nielsen *et al.*, 2006; Raghanti *et al.*, 2008). It reveals a dense and diverging projection of these brainstem neurons to all divisions of the adult brain. Anterograde and retrograde tracing techniques have revealed that serotonergic and non-serotonergic neurons of the raphe nuclei have overlapping projections. Subdivisions of the raphe nuclei have distinct projections predominantly focalized on restricted regions. Both immunocytochemistry and anterograde tracing techniques revealed that serotonergic axons have distinct morphologies (with thin or thick varicosities) (Kosofsky and Molliver, 1987; Törk, 1990; Ridet *et al.*, 1994). These two morphological types of serotonergic axons originate in separate raphe nuclei, and, due to the differential sensitivity of these two populations of serotonergic neurons to the specific neurotoxic agent MDMA, the preferential degeneration of serotonergic thin varicose axons reveals the arborization of the thick varicose axons (Kosofsky and Molliver, 1987; Ridet *et al.*, 1994). There is also a difference in the functional ultrastructure of the serotonergic varicosities; the majority (small size varicosities) are devoid of associated postsynaptic specializations, while some (large varicosities) form classical chemical synapses with postsynaptic neurons bearing a discrete postsynaptic differentiation (Törk, 1990; Ridet *et al.*, 1994; Smiley and Goldman-Rakic, 1996; see also Chapter 1.4 of this volume). Therefore, the relative density of serotonergic axons or varicosities defines either the functional organization of the serotonergic projection, if one considers a volume neurotransmission system of thin varicose axons, or the nature of the postsynaptic neurons in the case of large varicose axon projections.

The raphe nuclei of the rostral group have a projection primarily directed towards the forebrain, and to a lesser extent to the brainstem, while those of the caudal group primarily send projections to the lower brainstem and spinal cord (see below for a summary of the large body of literature dedicated to this topic). These two regions of the raphe system follow distinctive differentiation processes throughout their development (Lidov and Molliver, 1982; Aitken and Törk, 1988).

### **The rostral group**

#### *Efferent projections from the rostral group*

The rostral group has a major projection to the forebrain, ascending in two parallel pathways. The dorsal pathway is parallel to the medial longitudinal fasciculus, and collects the projections of the DR and the large multipolar serotonergic neurons of the MnR in the dorsolateral PnO, located near the DRVl (Azmitia *et al.*, 1986). The ventral

pathway is located on each side of the midline MnR, starting in the pons and reaching the ventral tegmental area, where it continues more rostrally into the medial forebrain bundle. The ventral pathway distributes principally to the basal forebrain and the medial cortex; the dorsal pathway approaches the medial forebrain bundle at the midbrain–forebrain junction, where it exchanges fibers with the ventral serotonergic pathway. At this level, a number of serotonergic axons enter the internal capsule to innervate the lateral cortex. In addition, the rostral group projects to the brainstem and to the spinal cord.

The anterior dorsal raphe nucleus projects principally to the cerebral cortex, the neostriatum, the amygdala and the substantia nigra (Steinbusch *et al.*, 1980; van der Kooy and Hattori, 1980; Waterhouse *et al.*, 1986; Vertes, 1991; Corvaja *et al.*, 1993). The caudal division of the dorsal raphe (DRC), extending into the pons, projects to the hippocampus, the entorhinal cortex and the locus coeruleus (Kohler and Steinbusch, 1982; Imai *et al.*, 1986; Datiche *et al.*, 1995; Vertes and Crane, 1997). There is some topographic organization of the serotonergic innervation to the cerebral cortex, mainly in the dorsal raphe, with a rostral to caudal gradient of the neurons relative to the innervation of the frontal to occipital cortex, respectively (Waterhouse *et al.*, 1986; Wilson and Molliver, 1991). The dorsal raphe also projects to the rostral cholinergic neurons (Gasbarri *et al.*, 1999), to the lateral septum or the striatum (Waselus *et al.*, 2006), to the thalamus (Westlund *et al.*, 1990; Gonzalo-Ruiz *et al.*, 1995), to the ependyma and to the subcommissural organ (Mikkelsen *et al.*, 1997; Simpson *et al.*, 1998). In the brainstem, it is also connected to cholinergic and non-cholinergic neurons of the lateral tegmental area (Steininger *et al.*, 1997), to the superior colliculus (Parsons *et al.*, 2001), to somatosensory, auditory, or vestibular nuclei (Thompson *et al.*, 1995; Simpson *et al.*, 2003; Halberstadt and Balaban, 2006; Lee *et al.*, 2008), as well as to motor nuclei of the brainstem (Li *et al.*, 1993; Lee *et al.*, 2008), to the cerebellum and to the spinal cord (Kazakov *et al.*, 1993; Li *et al.*, 1993; Petit *et al.*, 1995). A projection from DR and CLi to the bed nucleus of the stria terminalis is made by neurons containing the vasoactive intestinal neuropeptide (Petit *et al.*, 1995).

Multiple retrograde labeling revealed several collateralized projections involving the prefrontal cortex and the nucleus accumbens (Van Bockstaele *et al.*, 1993), the lateral geniculate nucleus and the superior colliculus (Villar *et al.*, 1988), the trigeminal nucleus and the central amygdaloid nucleus (Halberstadt and Balaban, 2006), the trigeminal nucleus and the facial nucleus (Lee *et al.*, 2008), the trigeminal nucleus and the spinal cord (Li *et al.*, 1993), or even the cerebral cortex and the spinal cord (Kazakov *et al.*, 1993). Finally, in parallel to the

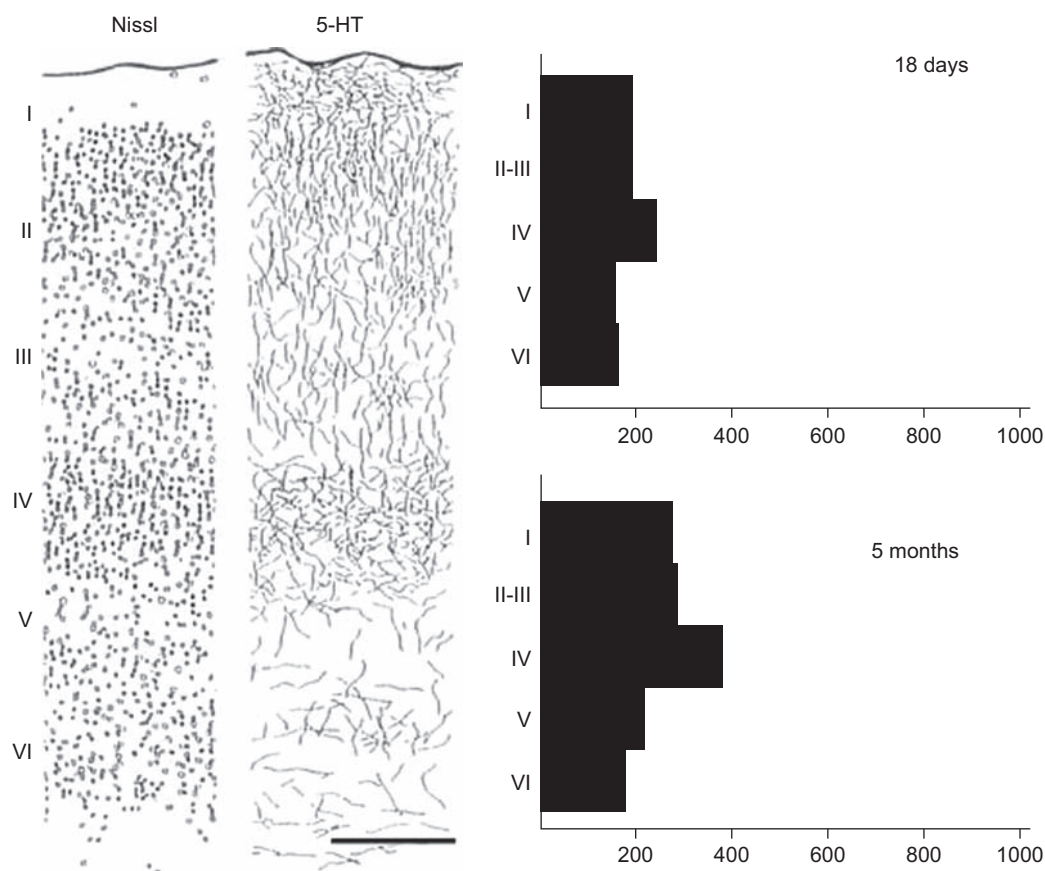

projection of serotonergic neurons, there is a contribution of non-serotonergic neurons to the projection to cortical and subcortical regions originating from the dorsal raphe nucleus (Datiche *et al.*, 1995; Aznar *et al.*, 2004; Halberstadt and Balaban, 2006, 2007, 2008).

The MnR is divided into a median and paramedian division with an ascending projection centered predominantly on the basal forebrain, the septal region, the ventral tegmental area, the hypothalamus, the midline thalamic nuclei and the hippocampus (Azmitia and Segal, 1978; Kohler *et al.*, 1982; Vertes and Martin, 1988; Vertes *et al.*, 1999). There is a projection of the MnR to the cerebral cortex, but with a sparse distribution as compared to the partially overlapping and complementary serotonergic projection of the dorsal raphe nucleus (Kievit and Kuypers, 1975; van der Kooy and Kuypers, 1979; Kohler and Steinbusch, 1982; Porrino and Goldman-Rakic, 1982; Tigges *et al.*, 1982; Datiche *et al.*, 1995; Vertes *et al.*, 1999). The projection of MnR on the rostral midline structure is supplemented with a projection on the raphe nuclei of the caudal and rostral groups, as well as the laterodorsal tegmental nucleus (Vertes *et al.*, 1999) and the cerebellum (Bishop and Ho, 1985; Kerr and Bishop, 1991). The ascending projection of MnR could modulate, directly and indirectly, the motor system and the basal ganglia by direct striatal projection and indirect nigral and intralaminar thalamic projection. Similarly, a direct hippocampal and indirect septal, mamillary and cingulate MnR projection could strongly modulate the limbic system. The suprallemniscal division of MnR contributes, together with serotonergic neurons located more dorsally in the MnR and DR, to the cerebellar innervation (Vertes and Crane, 1997).

The cerebral cortex, including the hippocampus, receives a strong serotonergic innervation from axons with various morphologies and specific laminar and areal distribution (Kievit and Kuypers, 1975; Kohler and Steinbusch, 1982; Porrino and Goldman-Rakic, 1982; Tigges *et al.*, 1982; O'Hearn and Molliver, 1984; Waterhouse *et al.*, 1986; Kosofsky and Molliver, 1987; Törk, 1990). The areal differentiation of the serotonergic innervation between cortical areas is particularly differentiated in the primate species (Morrison *et al.*, 1982; Takeuchi and Sano, 1983; Campbell *et al.*, 1987; Berger *et al.*, 1988; DeFelipe and Jones, 1988; Hornung *et al.*, 1990; Wilson and Molliver, 1991). Based on their morphology, serotonergic axons could be segregated into small varicose axons (less than 1 micron) and large varicose axons. Small varicose axons are widely distributed in all cortical areas, whereas large varicose axons are more restricted to layers in the hippocampus and the medial and frontal neocortex. The application of amphetamine-derived neurotoxins (p-chloroamphetamine

(PCA), 3,4-methylenedioxymethamphetamine (MDMA, ecstasy)) preferentially affects small varicose axons while leaving large varicose axons intact (Kosofsky and Molliver, 1987; O'Hearn *et al.*, 1988; Mamounas *et al.*, 1991). All cortical layers contain small varicose fibers, with distinctive patterns between areas. Characteristically, the laminar distribution of the serotonergic axons is highest in layer IV. The laminar distribution changes sharply between areas, and is most obvious at the transition between primary sensory and associative areas. The laminar pattern of serotonergic innervation of the prefrontal cortex increases in complexity and density in the human and great ape as compared to the innervation in the corresponding areas of the macaque monkey cortex, a differentiation which is not observed when comparing the serotonergic innervation of the motor cortex of the same species (Raghanti *et al.*, 2008). The laminar profile of the serotonergic axons is, for instance, already detectable 2 weeks after birth in the marmoset monkey, a New World primate, and will later sharpen into the adult laminar pattern (Figure 1). It suggests that the organization of the serotonergic innervation of the cerebral cortex is determined early during postnatal development but will further differentiate with the maturation of the cortical connectivity.

Large varicose axons form complex pericellular arrays closely surrounding neurons with the morphology of interneurons, and are shown to express the calcium binding protein calbindin or calretinin, but not parvalbumin, in the hippocampus of rodent and primates (Halasy *et al.*, 1992; Hornung and Celio, 1992; Miettinen and Freund, 1992; Acsady *et al.*, 1993). These large varicosities form classical chemical synapses onto the soma and dendrites of these interneurons. Calretinin- and calbindin-containing interneurons express the ionotropic 5-HT<sub>3</sub> receptor (Morales and Bloom, 1997), and are likely to mediate the serotonergic activation of GABA neurotransmission in the hippocampus (Ropert and Guy, 1991; Maeda *et al.*, 1994; McMahon and Kauer, 1997). Pericellular arrays have been visualized in the neocortex of cat (Mulligan and Törk, 1987), non-human primates (Hornung *et al.*, 1990; Wilson and Molliver, 1991; Jakab and Goldman-Rakic, 2000) and human (Kosofsky and Kowall, 1989; Hornung and De Tribolet, 1995; Trottier *et al.*, 1996). Electron microscopic studies of serotonergic axons have demonstrated that large varicosities in pericellular arrays indeed repetitively contact the same postsynaptic cell in forming classical chemical synaptic differentiation (Figure 2). Similar pericellular arrays of large varicose axons from serotonergic axons have been described in the lateral septum surrounding parvalbumin-containing neurons (Leranth and Vertes, 1999).

**Figure 1** Left: drawing of the 5-HT axons and the outline of cells (Nissl stain) defining the laminar boundaries in a coronal section through the superior temporal cortex of the marmoset monkey. Notice a salient granular layer (layer IV) corresponding to the densest meshwork of serotonergic axons. On the right, the profile of axonal density is quantified under microscope visualization, measured as the number of intersections by immunoreactive fibers on a grid placed in the ocular. In a young marmoset a characteristic profile is already distinctive from other neighboring cortical areas (not shown). A similar analysis in the 5-month-old marmoset shows clearly a maturation and augmentation of the fiber density, but still with a profile comparable to the one in neonatal animals. Scale: 150 microns.

#### *Afferent projections to the rostral group*

Although it is likely that the raphe nuclei share the basic architecture of the projections between mammalian species, most of our knowledge is based on tract-tracing studies made in rodents. In primates, the increased complexity of the raphe system projecting to the forebrain (see above) may lead to further differentiation in the organization of their afferents. The lateral habenula is a major source of afferents to DR and MnR (Behzadi *et al.*, 1990; Peyron *et al.*, 1998), a pathway using glutamate as neurotransmitter (Behzadi *et al.*, 1990). Both raphe nuclei also receive an input from the medial septum (Kalén and Wiklund, 1989) and the diagonal band of Broca and the ventral pallidum (Behzadi *et al.*, 1990; Peyron *et al.*, 1998). Several hypothalamic projections targeted to different divisions of the DR and MnR originate from nuclei in the medial and lateral pre-optic areas, the lateral, dorsal, ventral

and posterior divisions of the hypothalamus (Behzadi *et al.*, 1990; Peyron *et al.*, 1998; Lee *et al.*, 2003, 2005a, 2005b). There is an abundant GABAergic innervation of DR neurons (Wang *et al.*, 1992), and glutamatergic projections from the lateral habenula, the interpeduncular nucleus, several hypothalamic nuclei, the ventral tegmental areas, the laterodorsal tegmentum nuclei, and the cingulate cortex (Behzadi *et al.*, 1990). Stimulation of the medial prefrontal cortex inhibits the bursting of serotonergic neurons in the DR and MnR (Hajos *et al.*, 1998). The central nucleus of the amygdala projects to the DR (Peyron *et al.*, 1998; Lee *et al.*, 2007). There are, in addition, ascending projections to MnR originating from the RMg and RPa nuclei and from the nucleus prepositus hypoglossi (Behzadi *et al.*, 1990). Glycinergic projections to DR originate from the ventral and ventrolateral periaqueductal gray neurons and from neurons in the

**Figure 2** (A) Three-dimensional reconstruction of a cortical interneuron in layer II of the cat primary auditory cortex (green) contacted by varicose 5-HT-immunoreactive axons (red) at the surface of the soma and primary dendrites. (B) Micrograph of a coronal section in the marmoset frontal cortex containing 5-HT-immunoreactive thin and varicose axons, the latter forming conspicuous pericellular arrays surrounding tightly the cell body and proximal dendrites of individual neurons. (C) Electron micrograph of an unstained post-synaptic dendrite of a cat auditory cortex interneuron (D) forming a synaptic contact with a serotonergic large varicose immunoreactive axon terminal (arrowheads). Scale bar: for (A), 8 microns; for (B), 40 microns; for (C), 1 micron. To see the full color version of this figure please refer to the color plate at the back of the book. medullary rostral paragigantocellularis and rostral ventromedial reticular nuclei (Rampon *et al.*, 1999). Afferents from the medial nucleus of the solitary tract forward autonomic inputs to DR (Herbert, 1992).

### The caudal group

#### *Efferent projections from the caudal group*

The medullary raphe nuclei have major projections directed towards the caudal brainstem and spinal cord (Brodal *et al.*, 1960; Carlsson *et al.*, 1964; Skagerberg and Björklund, 1985). Retrograde labeling combined with 5-HT immunocytochemistry revealed that half of the raphe nuclei projecting to the spinal cord synthesize serotonin, a proportion that falls to a quarter in the lateral medullary neuron (Jones and Light, 1992).

Two populations of serotonergic axons project into the spinal cord. Axons bearing small varicosities are predominant in the dorsal division, and axons bearing large varicosities in the intermediate and ventral divisions of the spinal cord. Large varicose axons form classical chemical synapses onto the motoneurons (Ridet *et al.*, 1993). The ROb and the RPa provide the primary serotonergic input to the brainstem somatic motor nuclei, such as the motor trigeminal nucleus (Li *et al.*, 1993; Ribeiro-do-Valle, 1997), the facial nucleus (Arita *et al.*, 1993, 1995;

Li *et al.*, 1993), the retrofacial and the ambiguous nuclei (Arita *et al.*, 1993, 1995). In the spinal cord, it provides the innervation of the phrenic nucleus (Holtman *et al.*, 1990; Hosogai *et al.*, 1998) and the lumbar motoneurons (Tanaka *et al.*, 2006). There is also a projection to the autonomic motoneurons of the parasympathetic (dorsal vagal nucleus) and sympathetic (thoracic intermediolateral column, IML) systems (Loewy and McKellar, 1981; Poulat *et al.*, 1992; Yang *et al.*, 1994; Manaker and Fogarty, 1995). Serotonergic neurons projecting to the autonomic motoneurons co-localize the neuropeptide thyrotropin-releasing hormone (TRH) and SP (Poulat *et al.*, 1992; Wu *et al.*, 1993); those projecting to the somatic motoneurons lack SP (Wu *et al.*, 1993).

The raphe projections to the dorsal horn and dorsal column nuclei originated primarily from the RMg, and its serotonergic axons are devoid of TRH and SP (Wu and Wessendorf, 1992). In the sensory relays, there is a dense serotonergic innervation of laminae I and II of the spinal trigeminal nucleus (Costa *et al.*, 1994) spinal cord (Ridet *et al.*, 1993). The p-chloroamphetamine treatment has a similar selective neurotoxic effect as in the forebrain: the fine varicose serotonergic innervation disappears in the dorsal horn while sparing the large varicose serotonergic innervation in all divisions of the spinal cord (Ridet *et al.*, 1994). Inferring from the distribution of the serotonergic fibers in the spinal cord, the fine varicose fibers originate

primarily in RMg and the large varicose ones in ROb and RPa. The descending projections in the spinal cord follow two pathways: one lateral (and dorsal, depending on the authors) originates in the RMg and terminates in the dorsal horn, and one medial (and ventral) originates in the ROb and the RPa and terminates in the ventral horn and IML (Felten and Sladek, 1983; Azmitia *et al.*, 1986). There is a mixture of unmyelinated and partially myelinated descending serotonergic axons in the dorso-lateral tract (Westlund *et al.*, 1992; Leanza *et al.*, 1995). Although most raphe projections point toward the caudal divisions of the brain, serotonergic and non-serotonergic neurons of the caudal raphe nuclei send axon collaterals to both the lumbar intermediate and ventral gray matter and the medial pre-optic area of the hypothalamus (Leanza *et al.*, 1995). The RMg and RPa have ascending projections, in the rostral serotonin group, in the RMn (Behzadi *et al.*, 1990).

#### *Afferent projections to the caudal group*

Afferents to the anterior part of the caudal group (RMg, rostral RPa and Gia) originate in several hypothalamic nuclei, the dorsolateral periaqueductal gray, the central nucleus of the amygdala, the bed nucleus of the stria terminalis, and the medullary reticular formation (Zagon, 1993; Hermann *et al.*, 1997). Spinally projecting RMg and rostral RPa neurons receive direct catecholaminergic synaptic inputs (Tanaka *et al.*, 1994). The pneumotaxic area in the medial parabrachial area and the retrofacial nuclei has convergent inputs to the RMg (Gang *et al.*, 1993). There are also converging inputs onto RMg, ROb and RPa midline raphe neurons from visceral sensory afferents and ventrolateral periaqueductal gray matter neurons (Snowball *et al.*, 1997). The DR projects caudally on the RMg and ROb and LPGi (Vertes and Kocsis, 1994).

#### **Conclusions**

The serotonergic system is a collection of neurons and nuclei distributed along the brainstem in two groups sending projections in many directions, the rostral mainly ascending in the forebrain, the caudal with a major projection into the spinal cord. Each group subdivides further in subnuclei holding distinct sets of restricted afferent and efferent connections. Thus, serotonergic subnuclei are integrated components of, for instance, the cardio-respiratory system, the pain system, the motor system or the limbic system. This principle of organization accounts for the many functions with which serotonergic transmission is associated, and which are described in detail in the following chapters of this book.

In each of the regions or systems in which the serotonergic system is involved, the spatial pattern of the serotonergic afferents (regional and laminar specificity) positions the serotonergic input into the regulation of the system. The type of neurons connected (cellular specificity) and the type of serotonergic receptors associated (molecular specificity) contribute to the variety of cellular mechanisms modulated by serotonergic fibers.

The organization principles of the serotonergic system associate several parameters, such as the architecture of the connectivity, the expression pattern of serotonergic receptors and second messenger effectors in the various neuronal types of the target structure, with functional modulation of a system which will greatly vary from one area to the next. The following chapters will widely document these features in the various developmental, structural, physiological and pathological processes in which serotonin transmission is involved.

**Abstract:** In the past 40 years, cytochemical, radioautographic and immunocytochemical methods have been applied to identify serotonin (5-hydroxytryptamine, 5-HT) neurons at the electron-microscopic level, providing a wealth of information on their ultrastructural features in many parts of the mammalian central nervous system. This chapter summarizes much of these data, with an emphasis on the fine structural characteristics of 5-HT nerve terminals, particularly when they have been described in relation to chemically, physiologically or hodologically identified targets. Results obtained in various experimental models and during postnatal development have been included, as they provide insights into the morphological plasticity of the 5-HT system.

**Keywords:** axon terminals, cytochemistry, radioautography, immunocytochemistry, electron microscopy.

## Introduction

The serotonin (5-hydroxytryptamine, 5-HT) system is one of the most widespread transmitter-defined neuronal systems in the mammalian central nervous system (CNS). It is now clear that there is no single region of the CNS without 5-HT innervation, including the cerebro-ventricular cavity. Following the discovery of 5-HT neurons and the first anatomical description of their distribution as fluorescent microscopical silhouettes throughout the rat CNS (Dahlström and Fuxe, 1964; Fuxe, 1965), it did not take long before electron-microscopic methods were developed for their specific identification and characterization at the ultrastructural level (for review, see Beaudet and Descarries, 1987). Cytochemical, radioautographic and immunocytochemical approaches were then applied in that

order, yielding a wealth of information on the distribution, cytological features and ultrastructural relationships of 5-HT neurons in most parts of the CNS (Table 1).

The cytochemical technique was the first to demonstrate the 'axonal bouton' nature of the minute, evanescent, yellow fluorescent dots visualized with the histochemical fluorescence technique<sup>1</sup> (Hökfelt, 1967). However, it usually required immersion fixation procedures and/or the use of chemical markers of questionable specificity, and was soon replaced by the radioautographic technique after administration of tritiated 5-HT ([<sup>3</sup>H]5-HT) *in vivo*, which was compatible with perfusion fixation procedures for electron microscopy and yielded results of unsurpassed ultrastructural quality (reviewed in Descarries and Beaudet, 1983). [<sup>3</sup>H] 5-HT uptake radioautography could also be used on brain slices to quantify 5-HT innervation density (Doucet *et al.*, 1988). However, radioautography after [<sup>3</sup>H]5-HT uptake *in vivo* was technically demanding, and, because of the blood-brain barrier, its use was limited to brain regions accessible by cerebroventricular administration, topical application or local microinstillation of [<sup>3</sup>H]5-HT. In this context, the advent of immunocytochemistry in the late 1970s represented a major breakthrough, allowing for ultrastructural investigations of the 5-HT system in any CNS region, after immunolabeling with antibodies against

<sup>1</sup>Note: Throughout this chapter, the words 'nerve ending', 'terminal', 'varicosity', 'bouton' are used as synonyms to designate axonal enlargements containing aggregated small vesicles and endowed or not with the morphologically defined membrane specializations (junctional complex) that are the hallmark of synapses.

Review articles, theses and abstracts excluded, unless reporting data not published elsewhere.  
<sup>a</sup>Studies providing quantitative estimates of the synaptic incidence of 5-HT terminals (%), as directly observed in serial thin sections or extrapolated stereologically from single thin sections.  
<sup>b</sup>Studies combining techniques to identify targets of 5-HT axon terminals at the electron microscopic level.

the biosynthetic enzyme tryptophan hydroxylase (TPH) (Pickel *et al.*, 1976), 5-HT itself (Steinbusch, 1981), and more recently, the plasma membrane transporter of 5-HT (SERT) (Zhou *et al.*, 1998). Moreover, computer-assisted stereological techniques were developed for the unbiased count of neuronal cell bodies and axon terminals, which may now yield reliable estimates of 5-HT cell populations and density of 5-HT innervation in various parts of the CNS.

Looking back over the past forty years, it would seem that a huge amount of information has thus been gathered on the ultrastructure of the 5-HT innervation in the mammalian CNS (Table 1). Yet, it must be emphasized that most of these data come from rat, less frequently from cat and monkey, and that almost nothing is known for humans, because of technical difficulties in achieving adequate preservation of the fine structure of *post-mortem* brain tissue. Moreover, even in rat, many CNS regions have not been examined properly at the electron-microscopic level. It should also be noted that no ultrastructural studies of the 5-HT system have yet

been carried out in the mouse, in spite of its increasing use in genetic, neurobiological, behavioral, pathological and pharmacological investigations of the 5-HT system. Another caveat is that many ultrastructural studies have relied on a very restricted sampling and/or have merely sought to provide (illustrate) examples of morphological configurations that were expected in support of hypothetical connectional schemes.

Information on the ultrastructure of 5-HT neurons in mammalian brain has already been reviewed in some detail toward the end of the 1980s (Beaudet and Descarries, 1987; Soghomonian *et al.*, 1988; see also Maley *et al.*, 1990). For this reason, the present chapter will insist on data acquired since that time. Moreover, in summarizing these ‘new’ data, more attention will be paid to the relational than intrinsic (internal) morphological features of 5-HT axon terminals. The existence of axon terminals of different morphology in terms of size, shape and content of their small vesicles, and presence or absence of larger, granular (dense-core) vesicles, is no longer viewed as reliable evidence for a distinct chemical

identity or cellular origin of the corresponding neurons. Some 5-HT neurons have been demonstrated to send widely divergent projections to anatomical regions as distant from one another as the cerebral cortex and the spinal cord (Fallon and Loughlin, 1982; Kazakov *et al.*, 1993), in which axon terminals, albeit chemically defined, can hardly be expected to have the same morphology. Furthermore, progress in double-labeling techniques applicable at the electron-microscopic level has allowed for the combined demonstration of other transmitters and neuroactive molecules within 5-HT terminals, and for the physiological or hodological identification of neurons with which these are juxtaposed or in synaptic contact. This chapter will also pay particular attention to results obtained in various experimental models and during postnatal development, which provide insights on the morphological plasticity of the 5-HT system.

### 5-HT cell bodies and dendrites

Even if the common acceptance of the word innervation implies the release of transmitter by axonal nerve endings, there is strong evidence for a somatic and dendritic release of 5-HT by midbrain 5-HT neurons (Héry *et al.*, 1982), as initially demonstrated in the case of the dopamine neurons in ventral mesencephalon (Björklund and Lindvall, 1975; Cheramy *et al.*, 1981). This has prompted the search for organelles and/or membrane specializations equivalent to those observed at nerve terminals in ultrastructural studies of 5-HT mesencephalic nuclei. In rat, cat and monkey, 5-HT containing perikarya and dendrites of raphe dorsalis nucleus (DRN), whether identified by [<sup>3</sup>H]5-HT uptake radioautography (Beaudet and Descarries, 1981; Descarries *et al.*, 1982; Chan-Palay, 1982) or by 5-HT immunocytochemistry (Brusco *et al.*, 1983; Kapadia *et al.*, 1985; Pecci-Saavedra *et al.*, 1986; Chazal and Ralston, 1987) were often observed to be directly apposed to other neuronal somata or dendrites. These contacts are solely characterized by an interruption of the interneuronal glial sheath and juxtaposition of the plasma membranes, but, in cat, Chazal and Ralston have observed clusters of vesicles near the apposed plasma membranes of 5-HT immunoreactive dendrites (Chazal and O'Hara, 1986; Chazal and Ralston, 1987). Interestingly, in a subsequent study in the rat, Chazal and Ma (1989) did not find vesicular aggregates or membrane differentiations suggestive of synaptic specializations in 5-HT-immunolabeled dendrites of nucleus raphe magnus.

In rat, it was also observed that most of the somato-dendritic elements directly apposed to 5-HT perikarya or dendrites belong to non-5-HT neurons. In the rostral pole of the DRN, some of these apposed cells have been

identified as dopamine neurons by combined radioautography and tyrosine hydroxylase (TH) immunocytochemistry (Beaudet, personal communication). Differentiated synaptic contacts between adjacent 5-HT dendrites have, however, been described in monkey as well as in cat (Kapadia *et al.*, 1985; Chazal and Ralston, 1987). Direct juxtapositions of 5-HT dendrites were also observed in rat, but these appositions never showed junctional (synaptic) specializations (Descarries *et al.*, 1982). As the axonal 5-HT input to rat DRN is scarce (Descarries *et al.*, 1982) and 5-HT<sub>1A</sub> autoreceptors, known to control the firing and release of 5-HT neurons, are essentially somato-dendritic (Riad *et al.*, 2000), dendro-dendritic juxtapositions as well as junctions could represent the morphological substrate for this powerful auto- and mutual inhibition (Aghajanian *et al.*, 1972; Wang and Aghajanian, 1978, 1982).

### 5-HT innervation of the forebrain

#### Cerebral cortex

The 5-HT innervation of the cerebral cortex originates from the midbrain nuclei raphe dorsalis (DRN) and medianus (MRN), and spreads to every allo- and iso-cortical area (Andén *et al.*, 1966; Conrad *et al.*, 1974; Bobillier *et al.*, 1976; Beaudet and Descarries, 1976; Azmitia and Segal, 1978; Moore *et al.*, 1978; Lidov *et al.*, 1980; Steinbusch, 1981, 1984; Morrison *et al.*, 1982, 1984; Lindvall and Björklund, 1984). Areal and laminar differences in 5-HT innervation density have been documented in a quantitative radioautographic study of the anterior half of the rat cerebral cortex after [<sup>3</sup>H]5-HT uptake in slices (Audet *et al.*, 1989). The mean regional density of the cortical 5-HT innervation was then estimated at  $5.8 \times 10^6$  varicosities per mm<sup>3</sup> of tissue, with some variations between areas and layers. The highest laminar density was always that of layer I, except in pyriform cortex, and each region showed a distinct laminar pattern of 5-HT innervation. Such regional and laminar differences have been documented by histochemical fluorescence and 5-HT immunohistochemical studies in various species (see Chapter 1.3 of this volume). They appear to be even greater in the monkey than in the rat or cat cortex (Morrison *et al.*, 1982; Morrison and Foote, 1986; Campbell *et al.*, 1987), and need to be further documented in human brain (e.g., Trottier *et al.*, 1996; Austin *et al.*, 2002).

As shown in Table 1, both radioautography after [<sup>3</sup>H]5-HT uptake *in vivo* and immunocytochemistry with antibodies against 5-HT itself, TPH or SERT have been used to examine the fine structural features of these nerve terminals in various cortical areas of rats and Old

World monkeys. Electron-microscopic pictures of SERT-labeled axon terminals in the rat cerebral cortex have also been published by Yamamoto *et al.* (1998), and an ultrastructural 5-HT immunocytochemical study has also been carried out in cat auditory cortex (De Felipe *et al.*, 1991). However, throughout the literature, only one electron micrograph has been published of an axon terminal labeled with [<sup>3</sup>H]5-HT, in a pre-rolandic biopsy specimen of human cortex (Calas *et al.*, 1981).

The first electron-microscopic description of cortical 5-HT axon varicosities, identified in rat fronto-parietal cortex by radioautography after [<sup>3</sup>H]5-HT uptake *in vivo* (Descarries *et al.*, 1975; see also Beaudet and Descarries, 1978, 1981, 1984), revealed that, much like axon terminals of the peripheral autonomic nervous system, many of these CNS terminals lacked the localized plasma membrane specializations (junctional complex) that are the hallmark of synapses (Peters and Palay, 1996). Except for a few discordant reports, based on preliminary results (Molliver *et al.*, 1982) and early immunocytochemical data from the visual cortex of rat and monkey (Parnavelas *et al.*, 1985; Papadopoulos *et al.*, 1987a, 1987b; De Lima *et al.*, 1988), every subsequent study in which the synaptic incidence of cortical 5-HT varicosities was determined confirmed the partly or largely asynaptic character of this innervation, whether in rat, cat or monkey. In particular, the systematic 5-HT immunocytochemical survey of Séguéla *et al.* (1989), carried out in three regions of adult rat neocortex, evaluated the synaptic incidence of 5-HT varicosities at 36 percent and 28 percent in the superficial and deep layers of primary motor cortex respectively, 46 percent in the primary somato-sensory cortex, and 37 percent in the primary visual cortex (e.g., Figure 1A). The contacts formed by synaptic 5-HT varicosities were asymmetrical, and more frequently found on dendritic spines than dendritic branches, at least within the deep frontal and the upper occipital layers. Similar proportions of 5-HT varicosities (22 percent and 18 percent) were later reported to be synaptic in rat frontoparietal and entorhinal cortex after TPH immunolabeling (Cohen *et al.*, 1995). It should also be noted that, in the upper layers of all three cortical areas examined by Séguéla *et al.* (1989), unlabeled axonal varicosities, presumably non-5-HT, were frequently encountered juxtaposed to the 5-HT immunoreactive terminals. Such appositions between axon terminals could well provide for a distal pre-synaptic control of the release of other transmitters by 5-HT and, conversely, for a local control of 5-HT release by other cortical afferents. However, in a subsequent double-immunolabeling study by Miner *et al.* (2000), dopamine (TH immunoreactive) and 5-HT (5-HTT immunoreactive) axon terminals were rarely found to be juxtaposed, and

were typically separated by an average distance greater than 1  $\mu$ m in adult rat, prelimbic prefrontal cortex.

In cat auditory cortex, De Felipe *et al.* (1991) reported the existence of small, dense clusters of 5-HT immunoreactive varicosities, first described as baskets (Mulligan and Törk, 1987, 1988), around the somata and primary dendrites of cortical neurons, many of which were also shown to be immunoreactive to GABA. However, of 135 5-HT boutons examined in serial ultrathin sections, 110 of which belonged to these basket formations, only 4 were found making a synaptic contact, all asymmetrical. In cynomolgus monkey sensory-motor cortex, the same authors observed only 5 of 191 5-HT immunoreactive boutons reconstructed from serial sections showing a synaptic specialization; all of these were again asymmetrical (De Felipe and Jones, 1988). In the prefrontal cortex of rhesus monkey, Smiley and Goldman-Rakic (1996) found only 23 percent of 213 5-HT-immunostained varicosities completely viewed in serial sections making identifiable synapses. All contacts established by these synaptic 5-HT varicosities were again asymmetrical, and mostly formed with dendritic branches resembling those of interneurons.

In a more recent electron-microscopic immunocytochemical study of the rat visual cortex, Paspalas and Papadopoulos (2001) combined labeling with antibodies against 5-HT and against either neuropeptide Y (NPY), somatostatin (SRIF) or vasoactive intestinal polypeptide (VIP). Synaptic contacts were then demonstrated between some 5-HT terminals and the perikarya and proximal dendrites of NPY and SRIF neurons, as well as with the distal dendrites of SRIF neurons, but never with VIP elements. However, in another study in which the relationships between 5-HT afferents and various peptidergic-GABAergic interneurons of the rat cerebral cortex were examined by dual immunofluorescence confocal microscopy, many of the VIPs as well as SRIF and NPY neurons appeared to be innervated by 5-HT afferents (Cauli *et al.*, 2004).

Together with similar data from other parts of brain, the largely asynaptic character of the cortical monoamine and acetylcholine innervations may be viewed as crucial evidence for the existence of a diffuse mode of transmission in addition to synaptic transmission by these neuronal systems (for reviews, see Descarries *et al.*, 1991; Descarries and Umbriaco, 1995; Descarries and Mechawar, 2000, 2008). Currently available data on the subcellular localization of the different 5-HT receptors in mammalian CNS are consistent with this view (Descarries *et al.*, 1986). In all regions thus far examined, and irrespective of their subtype, some of the 5-HT receptors have been visualized on the plasma membrane of somata, dendrites, axonal fibers or axon terminals, but never at sites of junctional specialization.

## Hippocampus

The hippocampus has been shown by both radioautographic and immunocytochemical methods to receive a relatively dense 5-HT innervation (Azmitia and Marovitz, 1980; Lidov *et al.*, 1980, Köhler, 1984). In the dorsal hippocampus of rat, the regional and laminar distribution of this innervation has been quantified by radioautography after [<sup>3</sup>H]5-HT uptake in slices (Oleskevich and Descarries, 1990). The average density of 5-HT innervation in subiculum, Ammon's horn and dentate gyrus was then measured to be in the order of  $2.7 \times 10^6$  varicosities per mm<sup>3</sup>, but with values in the subiculum > in Ammon's horn > in dentate gyrus, and a marked heterogeneity in laminar distribution in each of these regions.

Few electron-microscopic investigations of the fine structure and cellular relationships of 5-HT nerve terminals in hippocampus have thus far been carried out, all of them in rat and with 5-HT immunocytochemistry, except for Cohen *et al.* (1995), who used TPH antibodies. In their initial report, Anderson *et al.* (1986) identified 5-HT axon terminals in the dentate gyrus (DG) of normal rats, but also in rats having received fetal raphe transplants after neonatal lesion of the fimbria-fornix and entorhinal cortex. Two categories of immunoreactive profiles were then observed: large ones, which never appeared to form synaptic junctions; and smaller ones, which occasionally showed asymmetrical synapses upon dendritic spines or small dendritic branches. These ultrastructural characteristics were found in both normal and grafted animals.

Oleskevich *et al.* (1991) provided a detailed description of the ultrastructural features of the 5-HT terminals in two major sectors of adult rat hippocampus, CA3 of Ammon's horn and the crest of DG; their description was completed by Umbriaco *et al.* (1995) with similar data from the stratum radiatum of CA1. The hippocampal 5-HT varicosities were then shown to be of comparable size in the three anatomical sectors and five neuropil layers examined, and ranged in synaptic incidence from 19 to 24 percent, whether extrapolated stereologically to the whole volume of varicosities from the synaptic frequency observed in single ultrathin sections, or directly observed in serial sections across whole varicosities (e.g., Figure 1B). A similarly low proportion of synaptic 5-HT varicosities (12 percent) was reported in the TPH-immunocytochemical study of Cohen *et al.* (1995), carried out in the CA1 region. As in the cerebral cortex, most if not all synaptic 5-HT varicosities formed asymmetrical junctions. In CA3, only dendritic shafts were contacted, but in CA1 and DG there were also a few axo-spinous 5-HT synapses. In both CA3 and DG, as in the cerebral

cortex, axonal varicosities were the most abundant neuronal element juxtaposed to the 5-HT-immunostained varicosities. Dendritic shafts were also relatively numerous, but dendritic spines infrequent. It is also noteworthy that in the rat hippocampus, as in the cerebral cortex of rat, cat or monkey, some GABAergic interneurons could be shown to be synaptically contacted by 5-HT varicosities in double-immunolabeling experiments (Freund *et al.*, 1990).

The ultrastructure of hippocampal 5-HT terminals has also been examined in a state of stabilized 5-HT hyperinnervation produced by a graft of fetal mesencephalic raphe neurons after previous cytotoxic destruction of the endogenous 5-HT innervation (Daszuta *et al.*, 1991). As in the previous study of Anderson *et al.* (1986), 5-HT terminals generated by the grafted 5-HT neurons were not found to differ significantly from normal, either in size or in synaptic characteristics. Despite the fact that they had grown in abnormal host tissue and in excessive number, they were apparently committed to express the same set of intrinsic and relational features as their normal phenotype.

## Olfactory bulb

In spite of its strategic location as initial relay in olfactory pathways and known innervation by 5-HT fibers originating from the midbrain raphe nuclei (Dahlström *et al.*, 1965; Araneda *et al.*, 1980), there has been only one ultrastructural study of the 5-HT innervation of olfactory bulb, carried out 30 years ago in the rat by Halász *et al.* (1978), using radioautography after *in vivo* labeling by local injection of [<sup>3</sup>H]5-HT. It was then shown that [<sup>3</sup>H]5-HT-labeled boutons in the glomerular layer formed axo-dendritic synaptic contacts with periglomerular cells, whereas in the external plexiform and internal granular layers they synapsed with dendritic shafts and spines of granule cells. Synapses on mitral cells were not demonstrated. This suggested that 5-HT effects in the olfactory bulb are exerted via interneurons. Whether some of the periglomerular cells contacted by 5-HT afferents belong to the distinct subpopulation synthesizing dopamine (Halász *et al.*, 1977; Ljungdahl *et al.*, 1977) remains to be demonstrated.

## Basal forebrain

The basal forebrain comprises the medial and lateral septum, the diagonal band of Broca, including the nuclei of its horizontal and vertical limbs, and the nucleus basalis. These brain regions contain cholinergic neurons, and have been shown to receive a prominent 5-HT innervation from the raphe medianus

(Moore and Halaris, 1975; Azmitia and Segal, 1978; Vertes and Martin, 1988).

An electron-microscopic study conducted in the rat medial septum and the diagonal band of Broca has shown symmetrical synaptic contacts between 5-HT immunoreactive axon varicosities and the soma-dendrites of neurons retrogradely labeled by axonal transport from the hippocampus of wheatgerm agglutinated apo-horseradish peroxidase conjugated to colloidal gold particles (Milner and Veznedaroglu, 1993). In accordance with this study, double-labeling experiments in these same brain areas have shown symmetric and asymmetric synaptic contacts made by 5-HT terminals with parvalbumin-containing GABAergic neurons (Léránth and Vertes, 1999) known to innervate the hippocampus (Naumann *et al.*, 1992; Peterson *et al.*, 1992) and to express 5-HT<sub>2A</sub> receptors (Léránth and Vertes, 1999). This circuitry is presumably involved in the well-known desynchronizing effects of the raphe medianus on the hippocampal electroencephalogram, thought to be important for mnemonic functions (for review, see Vertes and Kocsis, 1997).

Dinopoulos *et al.* (1993, 1997) have also used 5-HT immunocytochemistry to examine the ultrastructural features of the 5-HT innervation in rat lateral and medial septum, as well as in the diagonal band of Broca, with emphasis on their postnatal development. They observed the 5-HT varicosities in single thin sections, but took care to extrapolate the synaptic incidence for whole varicosities at various postnatal ages, from birth to adult. In the lateral septum, they thus demonstrated that, irrespective of age, virtually all 5-HT axon varicosities made symmetrical synapses, mostly with somata and proximal dendrites (Dinopoulos *et al.*, 1993). In the dorsal portion of the lateral septum, characteristic basket-like, pericellular arrangements were observed, as previously described for dopamine terminals (Descarries and Beaudet, 1983). In contrast, in the developing horizontal limb of the diagonal band of Broca, the synaptic incidence of 5-HT varicosities followed a biphasic temporal pattern: it increased gradually from birth, reached 43 percent at the end of the second postnatal week, declined markedly in the following week, and increased again to its adult value of 46 percent. At all postnatal ages, both symmetrical and asymmetrical contacts were established, mostly with a dendritic shaft (Dinopoulos *et al.*, 1997).

To our knowledge, there has been only one ultrastructural study attempting to characterize the 5-HT innervation of the nucleus basalis, where 5-HT is likely to modulate the function of cholinergic neurons projecting to the cerebral cortex (Smiley *et al.*, 1999). A synaptic contact made by a 5-HT axon varicosity was then observed in the nucleus basalis of Old World monkeys, but relatively poor ultrastructural preservation of the

tissue precluded a systematic characterization of this innervation.

### ***Bed nucleus of the stria terminalis***

As part of the limbic-hypothalamic-pituitary-adrenal system, the bed nucleus of the stria terminalis (BST) is tightly implicated in various visceral responses to stress and related behaviors. 5-HT innervation has been demonstrated by light- and electron-microscopic 5-HT immunocytochemistry in this nucleus, and shown to be denser in its medial than lateral subdivision (Phelix *et al.*, 1992). 5-HT varicosities in two size groups (large and small) were observed in the ventral BST, approximately 10 percent of which showed a synaptic specialization in single thin sections. These synaptic contacts were symmetrical or asymmetrical, and always made with dendritic branches. Even though some 5-HT varicosities were seen in close proximity to neuronal cell bodies, neither juxtapositions nor axo-somatic synapses were observed.

### ***Amygdala***

All subdivisions of the amygdalar complex receive a dense 5-HT innervation from the raphe dorsalis (Moore *et al.*, 1978; Steinbusch, 1981; Sadikot and Parent, 1990; Bauman and Amaral, 2005). In the basolateral amygdala of the rat, a double-labeling, immuno-electron microscopic study has shown that more than 75 percent of 5-HT immunoreactive axon varicosities formed synaptic junctions, which were mostly symmetrical, with dendritic spines and distal dendrites of pyramidal cells (Muller *et al.*, 2007). Interestingly, synaptic contacts were also observed with interneurons (Muller *et al.*, 2007), which have been reported to express 5-HT<sub>2A</sub> and 5-HT<sub>3A</sub> receptors in this part of the amygdala (Morales and Bloom, 1997; Mascagni and McDonald, 2007; McDonald and Mascagni, 2007). This could account for an indirect inhibition of pyramidal cells (Rainnie, 1999; Stutzmann and LeDoux, 1999) and a modulation of the activity of the basolateral amygdala in the generation of fast rhythmic oscillations during emotional arousal (Paré *et al.*, 2002; Muller *et al.*, 2005; Woodruff and Sah, 2007).

### ***Neostriatum***

The 5-HT innervation of mammalian neostriatum, first demonstrated in the rat by Fuxe and Jonnson (1967) using the histochemical fluorescence technique, was later shown to arise mainly from the raphe dorsalis and,

to a lesser extent, from the raphe medianus (Jacobs *et al.*, 1974, 1978; Lorens and Guldberg, 1974; Bobillier *et al.*, 1975, 1976; Kellar *et al.*, 1977; Azmitia and Segal, 1978; Moore *et al.*, 1978). This innervation appears rather uniformly distributed, without any suggestion of a patch and matrix organizational pattern (Soghomonian *et al.*, 1987). Its density increases from rostral to caudal, and is always higher ventrally than dorsally, ranging from  $4.8 \times 10^6$  varicosities per  $\text{mm}^3$  rostrally to  $6.3 \times 10^6$  caudally – an average of  $5.6 \times 10^6$  (Mrini *et al.*, 1995), almost the same as that in cerebral cortex.

Early electron-microscopic observations made in cat and rat after radioautographic labeling by topical and intraventricular administration of [ $^3\text{H}$ ]5-HT (Calas and Ségu, 1976; Calas *et al.*, 1976; Arluison and De La Manche, 1980), or later in cynomolgus monkey (*Macaca fascicularis*) after 5-HT immunocytochemistry (Pasik and Pasik, 1982; Pasik *et al.*, 1982, 1984), have suggested that neostriatal 5-HT terminals often lacked synaptic specialization in all three species. This was confirmed for rat in a detailed study where both methods were used in parallel to examine a significant number of [ $^3\text{H}$ ]5-HT-labeled varicosities from a paraventricular sector of neostriatum in single thin sections, and numerous 5-HT-immunostained varicosities from the same paraventricular sector plus a dorsal neostriatal sector in serial thin sections (Soghomonian *et al.*, 1989). The proportion of junctional 5-HT varicosities was then found to be very low, whether extrapolated stereologically from single sections (10 percent) or directly observed in serial sections (13 percent) (Figure 1C). The rare 5-HT synapses were equally distributed between dendritic spines and dendritic branches, and, as in the cortex, almost always asymmetrical. Whether synaptic or not, 5-HT varicosities were directly apposed to a variety of structures comprising mostly other axon terminals, dendritic spines and branches, but rarely neuronal somata. These appositional and synaptic relationships were similar in both the paraventricular and dorsal neostriatum, suggesting that throughout this brain region 5-HT transmission could be diffuse as well as synaptic, and might exert a distal control on the release of various transmitters through axo-axonic appositions.

Interestingly, as observed in the hippocampus after 5-HT grafts, no changes in either the intrinsic or relational features of 5-HT nerve terminals could be demonstrated in a state of stabilized 5-HT hyperinnervation induced by neonatal destruction of the nigrostriatal dopamine innervation with 6-hydroxydopamine (Descarries *et al.*, 1992), in spite of a twofold increase in the number of 5-HT terminals in the neostriatum of these rats (Mrini *et al.*, 1995). Also noteworthy was the report of Van Luijtelaar *et al.* (1991), who, in the sole ultrastructural study of a 5-HT innervation in aged rats, confirmed the above characteristics

for a majority of normal looking, thin varicose 5-HT immunoreactive fibers innervating the rat neostriatum, but also observed swollen 5-HT immunoreactive fibers containing distorted mitochondria and membrane-filled vacuole-like structures, suggestive of a degenerative process.

### *Nucleus accumbens*

Three immuno-electron microscopy studies have been published regarding the 5-HT innervation in nucleus accumbens. In the first study, by Van Bockstaele and Pickel (1993), care was taken to distinguish between the core of the nucleus, which is related to the caudate-putamen and involved in motor functions, and the shell region, which is associated with the limbic system and implicated in motivational processes. In the core, 5-HT immunoreactive varicosities appeared generally smaller than in the shell, and they contained fewer large dense core vesicles, assumed to transport biosynthetic enzymes and neuropeptides. The synaptic incidence of these terminals amounted to 39 percent and 46 percent in single thin sections of the core and the shell, respectively, which, unless due to a sampling bias, suggests that most if not all were synaptic. In both core and shell, the postsynaptic targets of 5-HT terminals were mostly large to medium-sized dendritic branches. Less than 2 percent were dendritic spines. In the core, synaptic contacts were mostly asymmetrical, whereas they were mostly symmetrical in the shell. Appositions with unlabeled terminals were frequent, and some could be shown to be TH immunoreactive (i.e., presumably dopaminergic) in double-immunolabeling experiments.

A subsequent double-immunolabeling study with anti-5-HT and anti-GABA antibodies also identified appositions and symmetrical synaptic contacts between 5-HT terminals and GABA-labeled and unlabeled dendrites in the shell region of the rat nucleus accumbens (Van Bockstaele *et al.*, 1996). Numerous 5-HT and GABA immunoreactive axon terminals were then observed in direct apposition to one another, suggesting distal interactions between the two systems.

5-HT terminals in the rat nucleus accumbens have also been identified in another immuno-electron microscopy study carried out with antibodies against the plasma membrane 5-HT transporter (SERT) (Pickel and Chan, 1999). It was then verified that the SERT-labeled axons and terminals did contain 5-HT in dual-immunolabeling experiments. As in the first immuno-electron microscopy study ever carried out with a SERT antibody (Zhou *et al.*, 1998), gold immunolabeling confirmed the predominant localization of the transporter to the plasma membrane of fine unmyelinated axons and their varicosities, away from synaptic specializations, which indicated that the SERT may

**Figure 1** Examples of immunoreactive 5-HT axon varicosities (terminals) in different anatomical regions of rat brain. Immunoperoxidase-DAB technique, with primary antibodies against 5-HT itself, in (A)–(C), and against the plasma membrane 5-HT transporter (SERT) in (D). (A) Cerebral cortex. This varicosity from layer VI of the frontal cortex is heavily labeled. Its roundish small vesicles, outlined by DAB precipitate, are barely discernible. It is directly apposed to another axon varicosity (av), unlabeled, and several small axonal and dendritic profiles. No synaptic junction was visible in four adjacent thin sections across this varicosity. From Séguéla *et al.* (1989). (B) Hippocampus. This presumed non-junctional 5-HT varicosity is from the stratum radiatum of CA1. It is juxtaposed to three unlabeled axon varicosities (av) and two dendritic branches (d). Its small vesicles are indistinguishable from those in other immunolabeled or unlabeled axon varicosities. From Umbriaco *et al.* (1995). (C) Neostriatum. Typical 5-HT varicosity from the middle third of neostriatum. Most neostriatal 5-HT varicosities are non-junctional. This one appears juxtaposed to a dendritic branch (d) and unlabeled varicosities (av). From Descarries, unpublished. (D) Subthalamic nucleus. This relatively small 5-HT varicosity, partly surrounded by a bundle of small, unmyelinated axons, is also juxtaposed to two dendritic branches (d). Scale bars: 0.5  $\mu\text{m}$ . From Parent *et al.*, unpublished.

not only play a role in terminating 5-HT synaptic transmission, but also regulate diffusely released and/or an ambient level of 5-HT (see also Tao-Cheng and Zhou, 1999).

### *Globus pallidus*

Even though the globus pallidus is known to receive a relatively dense 5-HT input, estimated at  $4.8 \times 10^6$  varicosities per  $\text{mm}^3$  of tissue in the rat (Soghomonian *et al.*, 1987),

little is known of the fine structural features of this innervation, which has only been examined in the monkey. In adolescent cynomolgus monkeys, Pasik *et al.* (1984) reported that 5-HT-immunolabeled fibers from this brain region formed large boutons, up to 1.5  $\mu\text{m}$  in diameter, making asymmetrical synaptic contact with dendritic shafts. These authors also observed crest synapses comprising an unlabeled terminal facing the 5-HT immunoreactive bouton contacting the same dendritic spines.

## Thalamus

The 5-HT innervation of the thalamus arises essentially from the raphe dorsalis, with minor contributions from the raphe medianus and the contralateral periaqueductal gray (Azmitia and Segal, 1978; Pasquier and Villar, 1982; De Lima and Singer, 1987b; Westlund *et al.*, 1990). The 5-HT fibers *en route* to the thalamus form a bundle that sweeps dorsoventrally within the midbrain tegmentum, and courses beneath the thalamus along its entire caudo-rostral extent. Several fiber fascicles break off from this main bundle at different levels, and ascend dorsally to pervade all thalamic nuclei (Lavoie and Parent, 1991). Within the thalamus, 5-HT axons are very thin, unmyelinated, and bear axon varicosities distributed at irregular intervals along their length. The regional density of 5-HT innervation varies markedly between thalamic nuclei (Cropper *et al.*, 1984). In the lateral geniculate nucleus (LGN) of the monkey (*Macaca nemestrina*), the density of 5-HT axon varicosities has been estimated at  $1.4 \times 10^6$  varicosities per  $\text{mm}^3$  of tissue (Wilson and Hendrickson, 1988).

Most ultrastructural studies of the 5-HT innervation in thalamus have focused on the LGN, whether in the rat (Papadopoulos and Parnavelas, 1990; Dinopoulos *et al.*, 1995; Dori *et al.*, 1998), cat (De Lima and Singer, 1987a) or monkey (Pasik *et al.*, 1988; Wilson and Hendrickson, 1988). The ventrobasal complex (Nothias *et al.*, 1988), the ventral lateral nucleus (Dori *et al.*, 1998) and the ventral posterior nucleus (Liu and Jones, 1991) have also been examined. In specific relay thalamic nuclei, varying proportions of 5-HT axon varicosities appeared to be endowed with a synaptic junction (Table 1). Except for one study, which claimed that all 5-HT varicosities in the rat LGN were synaptic when examined in serial sections (Papadopoulos and Parnavelas, 1990), all other studies carried out in single or serial thin sections reported partial values, notably that of Dinopoulos *et al.* (1995), who found a 42 percent incidence as stereologically extrapolated from single sections to the whole volume of varicosities (Dinopoulos *et al.*, 1995). The synaptic contacts established by thalamic 5-HT axon have been described as mainly asymmetrical and made with dendritic branches (De Lima and Singer, 1987a; Nothias *et al.*, 1988; Papadopoulos and Parnavelas, 1990; Liu and Jones, 1991; Dinopoulos *et al.*, 1995; Dori *et al.*, 1998).

In the study by Dinopoulos *et al.* (1995), the ultrastructural features of 5-HT terminals in the rat LGN were also examined during the postnatal period. Whereas only few axo-somatic symmetrical synaptic contacts had been observed in the adult rat LGN (Papadopoulos and Parnavelas, 1990), such contacts were frequently observed at the time of birth. As already described in the septum

and the diagonal band of Broca, the synaptic incidence of LGN 5-HT varicosities appeared to increase gradually from birth to reach a peak at the end of the second postnatal week (51 percent), and then declined markedly in the following week before increasing again to reach its adult value of 42 percent. This led to the speculation that synapses formed in the first 2 weeks could be primarily involved in morphogenetic effects of 5-HT, and those formed later with 5-HT neurotransmission. However, a comparable study carried out in the ventral lateral thalamic nucleus of the rat (Dori *et al.*, 1998) showed that in this nucleus, the proportion of 5-HT varicosities engaged in synaptic contact increased gradually from birth to adulthood, and that the length of synaptic junctions, the type of synaptic contacts and the nature of the postsynaptic elements remained unchanged throughout the development (Dori *et al.*, 1998).

It needs to be pointed out that some neurons, including thalamocortical neurons, which do not synthesize 5-HT, are able to take up and store 5-HT during the postnatal period in rat (Lebrand *et al.*, 1996, 1998; Cases *et al.*, 1998; Hansson *et al.*, 1998). Data based on the 5-HT or SERT immunocytochemical identification of terminals during postnatal development must therefore be regarded with caution. Some of the axon terminals which are then observed to be 5-HT or SERT immunoreactive might not be those of neurons that will later be part of the 5-HT system.

## Zona incerta

Two studies combining [ $^3\text{H}$ ]5-HT uptake radioautography and tyrosine hydroxylase immunocytochemistry have demonstrated the existence of direct appositions between 5-HT axon varicosities and dopamine cell bodies and dendrites in the medial zona incerta of rat. In both studies, carried out in single thin sections, only a few of the [ $^3\text{H}$ ]5-HT labeled varicosities were seen in synaptic junctions, which were all asymmetrical. Such observations were made in normal rats (Bosler *et al.*, 1983), but also in rats that had been treated with 5,7-dihydroxytryptamine 50 days earlier, and in which the examined terminals were those of regenerated axons (Frankfurt and Beaudet, 1988). This suggested the recapitulation of an innate program by 5-HT neurons, this time after partial lesion.

## Subthalamic nucleus

The 5-HT innervation of the subthalamic nucleus (STN) arises mainly from the raphe dorsalis (Lavoie and Parent, 1990). Although many electrophysiological studies have underlined the influence of 5-HT on the activity of STN

neurons (Stanford *et al.*, 2005; Xiang *et al.*, 2005; Shen and Johnson, 2008), there are not yet any data in the literature regarding the fine ultrastructural features of 5-HT axon varicosities in this key component of the basal ganglia (but see Wallman *et al.*, 2007). A preliminary study in our laboratory indicates that SERT immunoreactive axon varicosities are smaller in the rat than in the squirrel monkey (*Saimiri sciureus*) STN, but make synapses in a similar proportion (Figure 1D). The synaptic incidence extrapolated stereologically to the whole volume of varicosities is about 50 percent in both species. In monkeys, all junctions formed by the synaptic 5-HT varicosities are asymmetrical, compared to 77 percent in rats. In both species, synaptic junctions are almost equally shared between dendritic branches and spines. It is noteworthy that, despite a significantly higher density of 5-HT innervation in the anterior compared to the posterior half of monkey STN ( $1.7$  vs  $1.3 \times 10^6$  varicosities per  $\text{mm}^3$  of tissue, according to unbiased count under the light microscope), there are no significant differences between the ultrastructural features of these 5-HT varicosities, including synaptic incidence, in the two halves of STN. These similar findings in rat and monkey strongly suggest that the raphe dorsalis exerts its mixed electrophysiological effects on STN neurons through both synaptic delivery and diffusion of 5-HT, which may then reach 5-HT receptors on neighboring axonal afferents and provide for some local presynaptic inhibition.

### Hypothalamus

The hypothalamus receives a 5-HT innervation of variable density (Fuxe, 1965; Descarries and Beaudet, 1978; Steinbusch and Nieuwenhuys, 1981), which mainly originates from the midbrain and medial lemniscus 5-HT cell groups (group B9), as demonstrated after electrolytic lesioning of the nucleus raphe dorsalis and/or medianus (Aghajanian *et al.*, 1969; Kuhar *et al.*, 1972; Van de Kar and Lorens, 1979), or combined fluorescence 5-HT immunohistochemistry and retrograde transport labeling (Willoughby and Blessing, 1987). Thus far, all ultrastructural studies of hypothalamic 5-HT axon terminals have been carried out in the rat.

Rostrally, the *medial preoptic area* displays a moderate number of 5-HT terminals (Descarries and Beaudet, 1978; Steinbusch, 1984). In an electron-microscopic examination of this region after [ $^3\text{H}$ ]5-HT uptake radioautography, approximately one-third of 5-HT varicosity profiles displayed a synaptic specialization in single thin sections (Kiss and Halász, 1985), which suggests that most of them, if not all, were actually synaptic. After concomitant immunolabeling with specific antibodies against the luteinizing

hormone releasing hormone (LHRH), approximately 5 percent of [ $^3\text{H}$ ]5-HT-labeled terminals were found in contact, synaptic or not, with LHRH-immunostained dendrites, indicating that, in this hypothalamic area, 5-HT might directly act on LHRH neurons to regulate pituitary gonadotrophin secretion.

The *suprachiasmatic nucleus* (SCN) receives one of the densest 5-HT inputs in rat brain (Descarries and Beaudet, 1978; Steinbusch, 1981), particularly in its ventral part (see Descarries and Beaudet, 1978; Bosler, 1980). This innervation is believed to arise primarily from the raphe medianus (Van de Kar and Lorens, 1979), but also partly from the raphe dorsalis (Kawano *et al.*, 1996). Cytochemical approaches were first used for the electron-microscopic identification of 5-HT terminals in this nucleus (Ajika and Ochi, 1975; Nojyo and Sano, 1978). [ $^3\text{H}$ ]5-HT radioautographic studies followed, all of which combined the 5-HT labeling with that of another transmitter or neurohormone (Kiss *et al.*, 1984; Bosler and Beaudet, 1985a, 1985b; Bosler *et al.*, 1986). The 5-HT innervation of the rat SCN is only partly synaptic, as only 10 percent of axonal profiles labeled with [ $^3\text{H}$ ] 5-HT in this nucleus displayed a synaptic junction in single thin section, suggesting a synaptic incidence of at least 40 percent for the whole volume of these varicosities (Bosler and Beaudet, 1985a). This has been confirmed in a subsequent study of the synaptic connectivity of 5-HT graft efferents in the SCN as well as the supraoptic nucleus (SON) (Boulaïch *et al.*, 1994). Forty-eight percent of 5-HT immunoreactive terminals examined in serial sections were then found to make synapses in the SCN of normal rats, most of them with dendritic branches, and either symmetrical or asymmetrical. Interestingly, it has been reported that 5-HT axon terminals of the rat SCN lack monoamine oxidase B immunoreactivity, which is the type of monoamine oxidase found in 5-HT somadendrites (Arai *et al.*, 2002).

By combining [ $^3\text{H}$ ]5-HT labeling with vasoactive intestinal peptide (VIP) immunocytochemistry, it was shown that almost one-third of SCN 5-HT terminals were either directly apposed to or in synaptic contact with VIP immunoreactive neurons (Kiss *et al.*, 1984; Bosler and Beaudet, 1985a, 1985b; see also Bosler *et al.*, 1986). More than 60 percent of all synaptic contacts established by 5-HT axons were made with VIP neurons. These contacts were mostly found on dendrites, but a few were also observed on neuronal somata. 5-HT axons within the SCN were also shown by combined radioautography and immunocytochemistry to be directly apposed to glutamic acid decarboxylase (GAD) immunoreactive axon terminals (Bosler *et al.*, 1984a). Although deprived of synaptic specialization, such appositional contacts were suggestive of 5-HT/GABA interactions in the SCN,

where the 5-HT innervation is likely to be involved in a circadian regulation of gonadotrophin and prolactin secretion. Lastly, as illustrated in Figure 2A, it should be noted that in addition to synapses between 5-HT terminals and vasopressin immunoreactive dendrites, axo-axonic

synapses between 5-HT and vasopressin axon terminals might be present in the rat SCN (Bosler, personal communication).

An ultrastructural study of the 5-HT innervation has also been carried out in the *hypothalamic paraventricular nucleus*, which is moderately innervated by 5-HT fibers, particularly in its parvocellular subdivision (Descaries and Beaudet, 1978; Steinbusch and Nieuwenhuys, 1981). Using the immunoperoxidase-DAB technique with two chromogens to identify 5-HT terminals in conjunction with corticotropin releasing factor (CRF) elements, Liposits *et al.* (1987) described 5-HT immunoreactive boutons which formed synapses 'en passant' with dendrites and somata of parvocellular neurons. Moreover, some of these terminals made axo-dendritic and axo-somatic synapses with CRF immunoreactive neurons.

The *arcuate nucleus* also receives a moderately dense 5-HT innervation, which originates from both the raphe dorsalis and medianus (Van de Kar and Lorens, 1979; Willoughby and Blessing, 1987). In this nucleus, few of the varicosities labeled by [ $^3$ H]5-HT uptake *in vivo* were found to establish synaptic contacts, which again were mostly made with dendritic shafts (Kiss and Halász, 1986). Combined radioautographic and 5-HT immunocytochemical examination demonstrated the existence of direct appositions between [ $^3$ H]5-HT-labeled terminals and nerve cell bodies and/or dendrites of neurons immunoreactive for TH and therefore belonging to the A12 and A13 dopamine cell groups (Bosler *et al.*, 1984b, 1986; Bosler and Beaudet, 1985a; Kiss and Halász, 1986). Thus, 5-HT may be implicated in a direct, proximal control of dopamine neuron function within the arcuate nucleus, and potentially affect the dopamine regulation of prolactin, gonadotrophin and somatotrophin secretion. [ $^3$ H]5-HT-labeled varicosities have also been observed next to adreno-corticotrophic hormone (ACTH<sub>1-24</sub>) immunoreactive perikarya and dendrites within the rat arcuate nucleus (Kiss *et al.*, 1984; Bosler and Beaudet, 1985b). Most of these 5-HT varicosities were merely juxtaposed to the ACTH<sub>1-24</sub> containing neurons, but a few were seen in synaptic contact with their dendritic shafts.

The only study in which 5-HT terminals of the *supraoptic nucleus* (SON) have been investigated at the ultrastructural level is that of Boulaïch *et al.* (1994), who focused on eventual changes in the intrinsic and relational features of these terminals in the SCN and SON after 5-HT reinnervation and/or hyperinnervation by grafts of fetal neurons following an initial 5,7-dihydroxytryptamine lesion. Thirty-eight percent of serially sectioned 5-HT immunoreactive terminals in the SON of normal rats were then found to make synapses, almost always on dendritic shafts as opposed to spines, and more frequently symmetrical than asymmetrical. Interestingly, as in the SCN and

**Figure 2** Suprachiasmatic nucleus and raphe dorsalis nucleus. (A) Suprachiasmatic nucleus. This 5-HT immunoreactive axon terminal, labeled with the silver-intensified immunogold technique, is seen in synaptic contact (between small arrows) with an immunoperoxidase-DAB-labeled vasopressin immunoreactive profile (arrows) that appears to be axonal also. Note that these synaptic partners are almost totally enveloped by glial leaflets. Two other, vasopressin immunoreactive, axon-like processes are also visible (arrows), one of which (left) contains several large dense-cored vesicles. Reproduced courtesy of Olivier Bosler. (B) Raphe dorsalis nucleus. Two dendrites (d1 and d2), dually immunolabeled with primary antibodies against the 5-HT<sub>1A</sub> receptor (immunoperoxidase-DAB technique) and against the plasma membrane 5-HT transporter (SERT, immunogold technique), run normal to longitudinally sectioned unlabeled dendrites (d3 and d4). In d1, the plasma membrane localization of the SERT is obvious after its labeling with the immunogold technique. In contrast, the labeling of 5-HT<sub>1A</sub> receptors appears to be cytoplasmic, even if these receptors are known to be membrane bound, as visualized with the immunogold technique (Riad *et al.*, 2000). Note the synaptic contacts (between small arrows) made by unlabeled terminals (av) onto the lower, unlabeled dendritic branch (d3). These unlabeled terminals are morphologically similar to the one which contacts the dually labeled, 5-HT dendrite. Scale bars: 0.5  $\mu$ m. From Riad *et al.* (unpublished).

irrespective of the density of 5-HT re- or hyperinnervation, the synaptic incidence of the 5-HT terminals was remarkably conserved after grafting, as previously observed in the hippocampus under similar conditions (Daszuta *et al.*, 1991), or in the 5-HT hyperinnervated neostriatum after 6-OHDA destruction of nigrostriatal DA neurons (Descarries *et al.*, 1992). 5-HT synapses were mostly re-established with dendritic shafts, as in the normal innervation, but there was a tendency toward an increased number of symmetrical versus asymmetrical contacts in both the SON and SCN.

In an early histochemical fluorescence study after intraventricular administration of exogenous 5-HT (Fuxe and Ungerstedt, 1968) and subsequent radioautographic studies after intraventricular administration of [<sup>3</sup>H]5-HT (Descarries and Beaudet, 1978; Beaudet and Descarries, 1979; see also Beaudet and Descarries, 1981), a small population of neurons endowed with the capacity to take up exogenous 5-HT or [<sup>3</sup>H]5-HT was observed in the ventral part of the *dorsomedial nucleus* of adult rat hypothalamus, next to a particularly dense zone of innervation by [<sup>3</sup>H]5-HT-labeled terminals in the radioautographic study. However, these cell bodies had not been seen in earlier fluorescence histochemical studies of untreated rats; neither were they shown to contain endogenous 5-HT in subsequent 5-HT immunocytochemical studies (e.g., Steinbusch and Nieuwenhuys, 1981), except in rats treated with a monoamine oxidase inhibitor and the 5-HT precursor, L-tryptophan (Frankfurt *et al.*, 1981). It has not been determined what proportion of the [<sup>3</sup>H]5-HT-labeled terminals in the dense zone of presumed 5-HT innervation which was then observed at the electron-microscopic level might actually arise from the [<sup>3</sup>H]5-HT-labeled cells. The morphology of these terminals was not different from that in other hypothalamic regions. Some were occasionally observed to make symmetrical or asymmetrical synapses with unlabeled nerve cell bodies, but synaptic incidence was not evaluated (Beaudet and Descarries, 1979).

Frankfurt and Beaudet (1987) have examined the ultrastructural features of [<sup>3</sup>H]5-HT-labeled terminals in the dorsal part of the dorsomedial nucleus of hypothalamus at two survival times after a 5-HT denervation by intraventricular 5,7-dihydroxytryptamine – i.e., in a state of 5-HT reinnervation (30 days) and 5-HT hyperinnervation (50 days). At both survival times, as well as in controls, they found only a few synaptic contacts made by 5-HT varicosities, all axodendritic and asymmetrical, but an increase in the number of terminals abutting perikarya compared to the sham-treated rats. They concluded from these results that the 5-HT innervation in hypothalamus may regenerate with a great deal of cellular specificity.

### *Circumventricular organs*

The circumventricular organs are a series of midline structures located around the ventricular system and open to neuro-hemal exchanges. They comprise the median eminence, organum vasculosum laminae terminalis, subfornical organ, subcommissural organ, pineal gland and area postrema (see Calas *et al.*, 1978; Bouchaud and Bosler, 1986).

First demonstrated in the rat as degenerating nerve terminals after intraventricular administration of the selective neurotoxin 5,7-dihydroxytryptamine (Baumgarten and Lachenmayer, 1974), the 5-HT innervation of the *median eminence* (ME) predominates in its outer layer, the inner layer showing only scattered terminals (Calas, 1977; Jennes *et al.*, 1982). In rat and monkey, the 5-HT terminals in the outer layer were shown by electron-microscopic radioautography to contact the basement membrane of portal capillaries (Calas *et al.*, 1974; Calas, 1977; Nakai *et al.*, 1983), or to directly abut on tanyctic processes, but were never found to make a synaptic junction. Many were, however, directly juxtaposed to other axonal varicosities, some of which were later identified as containing thyrotropin-releasing hormone (TRH) (Nakai *et al.*, 1983), tyrosine hydroxylase or ACTH<sub>1-24</sub> (Bosler and Beaudet, 1985a), in combined radioautographic and immunocytochemical experiments. A light-microscopic study by Jennes *et al.* (1982) emphasized the considerable overlap between 5-HT and LHRH immunoreactive axon terminals in the rat ME, but axo-axonal synaptic contacts have never been demonstrated in the many electron-microscopic studies of this brain region. As suggested by Calas more than 30 years ago (1977), these observations suggested diverse modes of actions for 5-HT in the ME: (1) direct release in the portal system; (2) effects on the permeability of capillaries to various neurosecretory factors; (3) actions on tanyctic function; and (4) regulation of the release of hypophysiotrophic hormones or other transmitters through axo-axonic appositions.

Relatively dense 5-HT innervation has also been discovered by fluorescence histochemistry in the rat *organum vasculosum laminae terminalis* (OVLt) (Moore, 1977). In subsequent [<sup>3</sup>H]5-HT uptake radioautographic studies at the electron-microscopic level (Bosler, 1978, 1980; Calas *et al.*, 1978; Bouchaud and Bosler, 1986; Bosler and Descarries, 1988; Saïdi and Bosler, 1990), [<sup>3</sup>H] 5-HT-labeled terminals were found to represent almost 10 percent of all axon terminals in this brain region. They were most abundant in the rostrocaudal and ventrodorsal portions of the juxtaventricular zone, as well as in the dorsal aspect of the juxtavascular zone, but absent from the vascular core. In the juxtaventricular zone, a significant proportion made symmetrical or asymmetrical synapses

with dendritic shafts or spines, but none were ever seen in synaptic contact in the juxtavascular zone. In this latter zone, the 5-HT endings established close relationships with neurosecretory-like axons, and with astrocytic or tanyctic processes, with which they occasionally formed 'synaptoid' contacts. A few of these varicosities were also seen to abut directly on the outer basement membrane of the perivascular space. It is therefore likely that, in OVLT, 5-HT influences non-neural as well as neural elements. At a proximal level of regulation (juxtaventricular zone), it could act both synaptically and non-synaptically as interneuronal transmitter or modulator, whereas distally (juxtavascular zone) it could be released as a neurohormone in addition to modulating neurosecretion.

Interestingly, the 5-HT innervation of the OVLT has been shown to regenerate within several months after total destruction of its nerve terminals by cerebroventricular administration of 5,7-dihydroxytryptamine (Saïdi and Bosler, 1990). Sixteen months after the lesion, the regenerated terminals displayed a normal pattern of distribution and their ultrastructural features were similar to those of aged-matched controls, including their synapsing with dendritic shafts and spines in the juxtaventricular zone.

The rat *subcommissural organ* (SCO) also receives a relatively dense 5-HT innervation, arising mainly from the midbrain nuclei raphe dorsalis and medianus, with some contribution from the raphe pontis (Léger *et al.*, 1983). Within the SCO, these 5-HT terminals have been shown to establish asymmetrical synaptic contacts with both epen- and hypendymocytes (Bouchaud and Arluison, 1977; Bouchaud, 1979; Møllgård and Wiklund, 1979). More than 75 percent of axon terminals synapsing with SCO ependymocytes could be labeled with [<sup>3</sup>H]5-HT, suggesting that 5-HT plays a major role in regulating the secretory activity of these cells. According to Léger *et al.* (1983), the 5-HT afferents from the raphe dorsalis would inhibit the secretory activity of SCO ependymocytes, whereas those from the raphe medianus would exert the opposite effect. GABA uptake has also been demonstrated in some 5-HT fibers of the SCO (Gamrani *et al.*, 1981), but the functional significance of this co-localization remains to be determined.

The *subfornical organ* (SFO) appears to be sparsely 5-HT innervated in both radioautographic and immunohistochemical studies (Calas *et al.*, 1978; Takeuchi and Sano, 1983a; Tramu *et al.*, 1983). In the rat, [<sup>3</sup>H]5-HT-labeled boutons were mainly found beneath the ependyma and within the vascular region. In this zone, they approach fenestrated capillaries (Calas *et al.*, 1978). According to this author, some of the perivascular 5-HT fibers exhibit a discontinuous thickening of their membrane in front of the basal membrane surrounding the pericapillary space, whereas intraparenchymal 5-HT fibers occasionally

display synaptic-like differentiations (see also Bouchaud and Bosler, 1986). 5-HT terminals have also been identified by [<sup>3</sup>H]5-HT radioautography in the SFO of the monkey (Calas *et al.*, 1974).

In an early histochemical fluorescence study, Fuxe and Owman (1965) described a small group of indolaminergic, presumably 5-HT neurons in the rat *area postrema* (AP), located ventrally to the so-called A2 cell group of catecholaminergic neurons. Since then, the presence of these 5-HT cells has been confirmed by immunohistochemistry (Steinbusch, 1981; Tramu *et al.*, 1983), and the ultrastructural features of 5-HT axonal varicosities described by radioautography after intraventricular administration of [<sup>3</sup>H]5-HT, within the AP parenchyma or the pericapillary spaces (Pickel and Armstrong, 1984). In the parenchyma, these 5-HT varicosities frequently showed axo-dendritic synaptic contacts, whereas in the ventricular spaces they were described as free endings. Pickel *et al.* (1984) combined TH immunocytochemistry with the [<sup>3</sup>H]5-HT labeling to demonstrate that some of the axodendritic synapses in the parenchyma were made with catecholaminergic as well as non-catecholaminergic neurons. After combined radioautographic and immunocytochemical labeling, Armstrong *et al.* (1984) also observed the presence of enkephalin-like immunoreactivity in some of the 5-HT varicosities in AP.

### *Supra-ependymal plexus*

An extensive network of 5-HT axons forms a supra-ependymal plexus along the walls of the cerebral ventricles (Richards *et al.*, 1973; Lorez and Richards, 1973, 1975; Chan-Palay, 1976; Richards, 1977; Bosler, 1980; De La Manche *et al.*, 1981). These 5-HT fibers, which mostly originate from midbrain nuclei raphe dorsalis and medianus (Aghajanian and Gallagher, 1975), pervade most of the ventricular cavities, including the surface of the OVLT and of the SFO (Takeuchi and Sano, 1983a). They are absent beneath the SCO, but the ones seen along the lateral edge of the organ appear to be continuous with the dense plexus of hypendymal fibers (Møllgård and Wiklund, 1979; see also Bosler, 1980, and Takeuchi and Sano, 1983a). Electron-microscopic examination of supra-ependymal 5-HT varicosities after radioautographic [<sup>3</sup>H]5-HT uptake labeling in rat and monkey (Chan-Palay 1976; Richards, 1977; Calas *et al.*, 1978; Bosler, 1980; De La Manche *et al.*, 1981) has revealed that these varicosities are secured to the ependyma by small desmosomal-like attachment plaques, and devoid of synaptic specializations. The supra-ependymal 5-HT fibers in the rat have also been visualized with 5-HT immunohistochemistry (Richards *et al.*, 1981), and shown to take up

[<sup>3</sup>H]GABA (Gamrani *et al.*, 1984) and to be GABA immunoreactive (Harandi *et al.*, 1986). Striking pictures of these 5-HT fibers have also been obtained from *post-mortem* human brain by scanning electron microscopy (Richards *et al.*, 1980, 1981; see also Lorez and Richards, 1982).

Dinopoulos and Dori (1995) have also carried out a light- and electron-microscopic immunocytochemical study of the postnatal development of the supra-ependymal plexus in the lateral ventricles of the rat. They found this system to look morphologically mature by the end of the second postnatal week, and confirmed that its 5-HT varicosities, confined to the ventricular surface of the ependymal lining, never make synapses with the ependymal cells.

As initially described by Fuxe and Owman (1965) with the histochemical fluorescence technique, and later confirmed by 5-HT immunohistochemistry, there is a small group of several hundred 5-HT neuronal cell bodies, located ventrally to the A2 noradrenaline cell group, in the *area postrema* (AP) of the rat. 5-HT axon varicosities, labeled by [<sup>3</sup>H]5-HT uptake, have also been identified in the rat AP (Armstrong *et al.*, 1984; Pickel and Armstrong, 1984; Bouchaud and Bosler, 1986). These are located either in the parenchyma, where they frequently show axo-dendritic synaptic differentiations, or within the pericapillary and the ventricular spaces, in the form of free nerve endings. After combined radio-autographic and immunocytochemical labeling, Pickel *et al.* (1984) were able to demonstrate the existence of 5-HT terminals making synapses on dendrites of TH-immunoreactive (presumably noradrenergic) as well as non-catecholaminergic neurons in the rat AP, whereas Armstrong *et al.* (1984) reported that enkephalin-like immunoreactivity was occasionally present in some of these [<sup>3</sup>H]5-HT labeled terminals (see also Bosler *et al.*, 1986).

## 5-HT innervation of the brainstem

### *Substantia nigra*

The substantia nigra (SN) receives some of the densest 5-HT innervation in the brain (Fuxe, 1965; Steinbusch, 1981) arising primarily from the mesencephalic raphe nuclei (Bobillier *et al.*, 1976; Fibiger and Miller, 1977; Azmitia and Segal, 1978; Parent *et al.*, 1981; Lavoie and Parent, 1990; Vertes, 1991). In monkey as well as rat, its pars reticulata is more densely innervated than its pars compacta (Pasik *et al.*, 1984). In the rat, Moukhles *et al.* (1997) have quantified the density of this innervation at  $9 \times 10^6$  and  $6 \times 10^6$  varicosities per mm<sup>3</sup> of tissue in reticulata and compacta, respectively.

Following an early radioautographic study demonstrating the existence of labeled terminals forming

axo-dendritic synaptic contacts in the substantia nigra of rats administered [<sup>3</sup>H]5-HT in a lateral ventricle of the brain (Parizek *et al.*, 1971), the ultrastructure of these 5-HT terminals has been examined by 5-HT immunocytochemistry in the rat and guinea pig as well as in the monkey (Table 1). In both pars reticulata and compacta of rat SN, Mori *et al.* (1987) and Corvaja *et al.* (1993) noted the presence of many 5-HT varicosities which made synaptic contact mostly with dendritic shafts and occasionally with dendritic spines (Corvaja *et al.*, 1993), and similar observations were made in the pars reticulata of the monkey's SN (Pasik *et al.*, 1984). Subsequently, the study of Moukhles *et al.* (1997) revealed a striking difference between the 5-HT varicosities in the two subdivisions of rat SN. As extrapolated stereologically to the whole volume of these varicosities, virtually all 5-HT varicosities in the pars reticulata, but only 50 percent of those in the pars compacta, formed synapses, essentially with dendritic branches. By combining the immunogold labeling of tyrosine hydroxylase (TH) with 5-HT immunoperoxidase labeling, these authors also confirmed an earlier observation of Nedergaard *et al.* (1988) of synaptic contacts between 5-HT terminals and dopamine (TH immunoreactive) dendrites in the guinea pig. In rat, they found that 20 percent of the synaptic 5-HT terminals in the pars reticulata contacted dopamine dendrites, and that a smaller percentage (6 percent) was in contact with unlabeled dendrites characterized by an unusually high cytoplasmic content in neurotubules.

Interestingly, Bunin and Wightman (1998) then used fast-scan voltammetry to compare 5-HT uptake and release in the pars reticulata of substantia nigra, in which all 5-HT terminals appear to be synaptic, to that in the raphe dorsalis, a somatodendritic region with rare synaptic 5-HT varicosities. The conclusion from their study was that diffuse 5-HT transmission occurred in both regions, suggesting that this mode of transmission might apply to synaptic as well as non-synaptic 5-HT terminals.

### *Ventral tegmental area*

The ventral tegmental area (VTA), which contains the largest collection of dopamine-containing neurons in the brain (group A10, according to the nomenclature of Dahlström and Fuxe, 1964), also receives relatively dense 5-HT innervation from the raphe dorsalis and medianus. Two radioautographic studies after intraventricular administration of [<sup>3</sup>H]5-HT *in vivo* have described the ultrastructural features of this 5-HT innervation in the rat (Hervé *et al.*, 1987; Van Bockstaele *et al.*, 1994; see also Bosler *et al.*, 1986). Hervé *et al.* (1987) demonstrated

that more than 18 percent of these terminals showed a synaptic specialization in single thin sections, allowing the extrapolation that 50 percent were actually synaptic. Most of these synapses were asymmetrical, and formed with dendritic shafts. After concomitant immunolabeling for TH, it was apparent that some were made with the dendrites of dopamine neurons and others with non-dopamine dendrites. Similar observations were made by Van Bockstaele *et al.* (1994), who showed, in addition, that many of the neurons contacted by 5-HT immunoreactive terminals were labeled by retrograde axonal transport of gold-conjugated wheatgerm agglutinin injected into the nucleus accumbens. Thus, within the VTA, synaptic as well as non-synaptic release of 5-HT might modulate mesolimbic as well as mesocortical efferent systems.

### *Nucleus interpeduncularis*

Presumed 5-HT axon terminals have also been visualized in the interpeduncular nucleus of the rat by Nojyo and Sano (1978) in their cytochemical study of the suprachiasmatic nucleus after loading with 5,6-dihydroxytryptamine. These authors described these 5-HT terminals as less frequently synaptic than in the suprachiasmatic nucleus.

### *Red nucleus*

Even though 5-HT exerts various electrophysiological effects when applied iontophoretically into the red nucleus of cat or rat (Davis and Vaughan, 1969; Schmied *et al.*, 1991; Licata *et al.*, 1998), the density of 5-HT innervation appears to be moderate in this brain region (Steinbusch, 1981). Bosler *et al.* (1983) have described the ultrastructural features of this 5-HT innervation in the cat, after its radioautographic labeling by [<sup>3</sup>H]5-HT uptake *in vitro*. Symmetrical synaptic junctions were then reported to be made by 5-HT axon varicosities, with small dendritic processes and with the cell bodies and large dendritic trunks of magnocellular neurons. In contrast, in a subsequent 5-HT immunocytochemical study of the rat red nucleus, 5-HT axon varicosities were not found to establish any clearly defined synaptic junction, indicating a very low synaptic incidence (André *et al.*, 1987). These authors also combined 5-HT with GABA immunolabeling to demonstrate occasional contacts between the 5-HT endings and dendrites of large-sized neurons receiving a GABA input, as well as direct appositions between 5-HT and GABA positive terminals, suggesting that red nucleus output may be dually regulated by 5-HT and GABA

afferents and that distal axonal interactions might also play a role in red nucleus function.

### *Oculomotor nucleus*

The density of 5-HT innervation in the rat oculomotor nucleus has been rated as low to medium, with a rostro-caudal decreasing gradient of distribution (Steinbusch, 1981). In the only electron-microscope radioautographic study of this nucleus, following local administration of [<sup>3</sup>H]5-HT *in vivo*, Soghomonian *et al.* (1986) observed that about 50 percent of its 5-HT axon varicosities profiles exhibited a synaptic membrane differentiation in single thin sections, suggesting an entirely synaptic innervation and the frequent occurrence of more than one junction per varicosity. The synapses were predominantly asymmetrical when formed with small to large dendritic shafts, and exclusively symmetrical onto dendritic spines. A few 5-HT axon varicosities in synaptic contact with unlabeled cell body were also observed (Soghomonian *et al.*, 1986). This study suggests that, as in other motor nuclei (see below), 5-HT transmission is mostly synaptic within the oculomotor nucleus.

### *Superior colliculus*

The mammalian superior colliculus receives multiple inputs that include projections from the retina, the visual cortex and the lateral geniculate nucleus. This laminated structure is well known to play a crucial role in the processing of information directing gaze toward objects of interest (McPeck and Keller, 2004). Its 5-HT innervation, which is particularly dense in the superficial layers (Fuxe, 1965), comes mainly from the raphe dorsalis, but also from the raphe medianus, raphe pontis and contralateral periaqueductal gray (Beitz *et al.*, 1986; Villar *et al.*, 1988; Mize and Horner, 1989).

Immuno-electron microscopy experiments conducted in the superior colliculus of the rat (Dori *et al.*, 1998), cat (Mize and Horner, 1989) and hamster (Arce *et al.*, 1992, 1995; Crissman *et al.*, 1993) have revealed that many of the 5-HT axon varicosities in this nucleus do not display synaptic junctions. As measured in single thin sections, the reported synaptic incidences for these terminals ranged from 4 percent in the hamster (Arce *et al.*, 1992, 1995; Crissman *et al.*, 1993) to 22 percent in the rat (Dori *et al.*, 1998). Only 3 of 50 5-HT axon varicosities examined in serial thin sections in the superficial layers of the hamster's superior colliculus were synaptic (Arce *et al.*, 1992), but, in the rat, stereological extrapolation to the whole volume of varicosities indicated a synaptic

incidence of 55 percent (Dori *et al.*, 1998). In both superficial and deep layers of the rat superior colliculus, the majority of these synapses were symmetrical and made with dendritic shafts. Symmetrical or asymmetrical synapses on spines were also occasionally observed, but the rare synapses on cell bodies were exclusively symmetrical (Dori *et al.*, 1998). In the rat (Dori *et al.*, 1998), as well as the cat (Mize and Horner, 1989) and hamster (Arce *et al.*, 1995), 5-HT axon varicosities were often seen juxtaposed to unlabeled axonal profiles, and some of these axo-axonal contacts were described as synaptic (Arce *et al.*, 1995; Dori *et al.*, 1998). 5-HT<sub>1B</sub> receptor binding sites have been demonstrated on retinocollicular afferents (Ségu *et al.*, 1986; Boulenguez *et al.*, 1993, 1996; Sari *et al.*, 1999), supporting the possibility of a distal, inhibitory gating of visual inputs by 5-HT.

As in the septum, the diagonal band of Broca and lateral geniculate, Dori *et al.* (1998) reported that the synaptic incidence of 5-HT axon terminals in the superficial layers of the developing superior colliculus of the rat increases markedly from birth to the end of the first postnatal week, and then decreases for 2 weeks prior to a further increase to its adult value. The first phase of synapse formation would coincide with the arrival of cortical and retinal afferents in the superior colliculus, which supports an influence of 5-HT in the development of these afferent projections (Rhoades *et al.*, 1993; Ke *et al.*, 1999). In contrast, the earlier studies conducted in the hamster superior colliculus had rather suggested a gradual age-related increase in the density of 5-HT innervation with a gradual decrease in the synaptic incidence measured in single thin sections, from 37 percent in the newborn to 4 percent in the adult (Crissman *et al.*, 1993). Rather than a progressive loss of synaptic contacts, this latter result could point to a progressive dilution of the synaptic 5-HT innervation by later-arriving 5-HT afferents that do not make synapses. The idea of a competition for synaptic sites between 5-HT axon varicosities and retinal afferent projections has been tested by postnatal enucleation in adult and newborn hamsters. Removal of retinal afferent projections at birth resulted in an increased density of 5-HT innervation and of their synaptic incidence, as measured in single thin sections, from 4 percent to 18 percent in adult hamsters (Arce *et al.*, 1995).

### ***Dorsal periaqueductal and central gray***

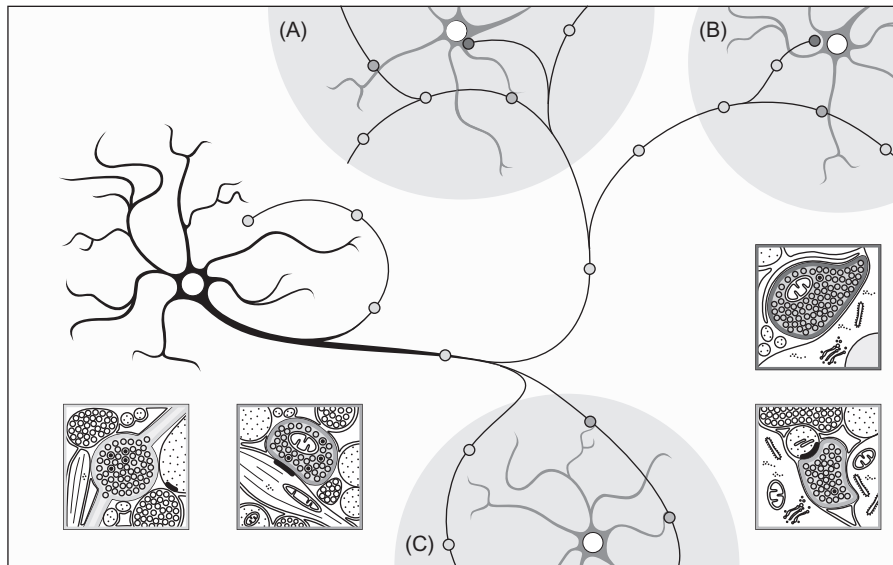

It is in the central gray of rat brainstem that axon terminals having taken up [<sup>3</sup>H]5-HT were visualized for the first time by high-resolution radioautography (Aghajanian and Bloom, 1967). Almost 20 years later, a detailed light- and electron-microscopic 5-HT immunocytochemical

study of the rat midbrain periaqueductal gray (PAG) was carried out by Clements *et al.* (1985). In this study, synaptic contacts established by 5-HT axon varicosities were rare. Similar observations were subsequently made by Lovick *et al.* (2000), who focused on the dorsolateral PAG and examined the ultrastructural relationships of 5-HT terminals in brain slices in which some PAG neurons had been filled with biocytin, but also in specimens from perfusion-fixed whole brain. In serial sections across 21 5-HT terminals apposed to biocytin-filled dendrites, these authors found only 4 displaying synaptic specialization, and they reported a similar synaptic incidence of 23 percent in the better-preserved material from whole brain.

### ***Nucleus raphe dorsalis***

In all raphe nuclei containing 5-HT neurons, the latter are found among numerous non-5-HT cell bodies. For instance, in the rat raphe dorsalis, 5-HT cells account for approximately one-third of a total population of 36,000 neurons (Descarries *et al.*, 1982), some of which are now known to be GABAergic or glutamatergic (Commons and Valentino, 2002; Commons *et al.*, 2005). Even though not numerous, 5-HT axon terminals have been identified in the rat, cat and monkey raphe dorsalis, either with [<sup>3</sup>H]5-HT uptake radioautography or with 5-HT immunocytochemistry (Chan-Palay, 1982; Descarries *et al.*, 1982; Chazal and Ralston, 1987). As interconnections have been demonstrated between the different raphe nuclei (Bobillier *et al.*, 1976), some of these terminals could be those of 5-HT afferents from other 5-HT cell groups, and others of recurrent collaterals issued by intrinsic 5-HT neurons (Mosko *et al.*, 1977; Kalén *et al.*, 1985). Whatever their origin, 5-HT terminals in the raphe dorsalis make only rare synaptic specializations, which also seems to be the case in rat raphe magnus (Chazal and Ma, 1989). In both nuclei occasional synaptic contacts have, however, been observed between 5-HT terminals and unidentified dendritic branches, as well as with tyrosine hydroxylase immunoreactive dendrites within raphe dorsalis (see Soghomonian *et al.*, 1988), which presumably belong to the small population of dopamine neurons residing in the rostral pole of this nucleus (Descarries *et al.*, 1986).

In keeping with earlier radioautographic observations of [<sup>3</sup>H]5-HT uptake by 5-HT neurons in the raphe dorsalis and the notion of a somatodendritic release of the transmitter, 5-HT transporter (SERT) has been shown to be present all along the plasma membrane of these neurons, including the soma-dendrites (Figure 3A), and not only on axons and axon terminals in territories of innervation. By dual-immunocytochemical labeling, it has also been possible to demonstrate the presence of 5-HT<sub>1A</sub> autoreceptors

**Figure 3** Schematic representation of a 5-HT neuron. As depicted here, a single 5-HT neuron may innervate different anatomical regions (A, B, C), including its nucleus of origin (through recurrent collaterals of its axon). In the territories of innervation, many of the 5-HT varicosities (small colored dots), distributed as rosary beads on distal branches of the axon, do not make synaptic contact (yellow dots). Others are endowed with junctional complexes, the small zone of membrane specialization, either symmetrical or asymmetrical, that is the hallmark of synapses, and make such a contact with dendritic branches (green dots), and, more rarely, dendritic spines (blue dots). Juxtapositions to cell bodies are also seen (red dots). These various configurations, schematized in the boxes, may be found within a given anatomical territory, and probably on a single axonal branch. The vesicular content of 5-HT varicosities may also vary from one anatomical region to another, and in some regions, such as the cerebellum with its mossy 5-HT fibers, or the locus coeruleus and its 5-HT varicosities filled with microvesicles and canaliculi, 5-HT terminals of a unique morphology may be found. It has been calculated that some 5-HT neurons may possess as many as hundreds of thousands axon varicosities (Descarries *et al.*, 1990). The demonstration of the existence of asynaptic 5-HT varicosities in mammalian CNS was at the origin of the concept of diffuse (volume) transmission (for review, see Descarries and Mechawar, 2000). To see the full color version of this figure please refer to the color plate at the back of the book. Copies produced via our print on demand service do not contain color plates; if your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

on the soma-dendrites of the raphe dorsalis 5-HT neurons decorated with SERT (Figure 2B).

### *Locus coeruleus*

The locus coeruleus is the major group of noradrenergic neurons in mammalian brain (A6, in the nomenclature of Dahlström and Fuxe, 1964). It receives a dense 5-HT innervation, which appears to originate from three raphe nuclei: the raphe dorsalis, raphe medianus and raphe pontis (Léger *et al.*, 1980). This 5-HT innervation has been characterized at the electron-microscopic level in the rat, using both TPH immunocytochemistry (Pickel *et al.*, 1977) and radioautography after *in vivo* uptake of [ $^3$ H] 5-HT (Léger and Descarries, 1978; see also Descarries and Léger, 1978). Its varicosities are often asynaptic, but some do establish typical asymmetrical synapses with dendritic branches and spines presumably belonging to noradrenergic neurons. Thus, both diffuse and synaptic 5-HT transmission might contribute to the modulatory

effects of 5-HT on noradrenergic neurons (see, for example, Guiard *et al.*, 2008).

### *Mesopontine tegmentum*

The 5-HT neurons located in the raphe dorsalis are also known to innervate the pedunculopontine and laterodorsal nuclei, and double-immunolabeling for electron microscopy has allowed for the demonstration of synaptic contacts between 5-HT axon varicosities and the cholinergic neurons in these two nuclei (Honda and Semba, 1994; Steininger *et al.*, 1997; Wang *et al.*, 2000). Both symmetrical and asymmetrical synaptic contacts were observed, which were mainly located on proximal dendrites and cell bodies (Honda and Semba, 1994; Steininger *et al.*, 1997). These observations were consistent with electrophysiological studies showing that 5-HT-induced hyperpolarization of cholinergic laterodorsal neurons involves a direct action of 5-HT (Luebke *et al.*, 1992), and with the suggested a role of the raphe dorsalis in the modulation of rapid eye

movement (REM) sleep through this direct action (Steriade and McCarley, 2005). Electrophysiological studies have also suggested that 5-HT-induced hyperpolarization of cholinergic laterodorsal neurons might involve a direct action of 5-HT on these neurons (Luebke *et al.*, 1992). Interestingly, in the rostral laterodorsal tegmental nucleus a few 5-HT cell bodies and dendrites are present (Honda and Semba, 1994), and some of the 5-HT dendritic shafts contain aggregated synaptic vesicles, as already observed in the raphe nucleus of the cat (Chazal and O'Hara, 1986; Chazal and Ralston, 1987) and monkey (Kapadia *et al.*, 1985). It is therefore likely that somatodendritic as well as axonal release of 5-HT takes place in this nucleus.

### ***Paragigantocellularis lateralis and paratrigeminal nuclei***

The nucleus *paragigantocellularis lateralis* of the medullary reticular formation contains 5-HT neurons that were first identified as the B3 group by Dahlström and Fuxe (1964). The fine ultrastructural features of these neurons and axon terminals in this nucleus have been described in a radioautographic study conducted by Chan-Palay (1978a) in rhesus monkeys. Prominent axo-axonic as well as symmetrical and asymmetrical axo-dendritic synaptic contacts were then observed to be made by these 5-HT varicosities, whose synaptic incidence was reported to be as high as 84 percent in two adjacent thin sections, suggesting the existence of multiple synaptic junctions on many of these varicosities.

In another radioautographic study following injection of tritiated 5-HT in the *paratrigeminalis nucleus* of the rat and monkey, Chan-Palay (1978b) described the 5-HT varicosities of this nucleus as making not only axo-dendritic and axo-spinous but also axo-somatic synaptic contacts. She then estimated at 60 percent the synaptic incidence of these 5-HT varicosities in adjacent thin sections.

### ***Trigeminal nuclei***

The trigeminal nuclear complex extends throughout the entire brainstem and merges caudally with the dorsal horn of the spinal cord. Its three nuclei, the mesencephalic, spinal and motor trigeminal, all receive a dense 5-HT innervation mainly from the raphe dorsalis (Tashiro *et al.*, 1989; Copray *et al.*, 1991).

In the *mesencephalic trigeminal nucleus*, the synaptic incidence of 5-HT varicosities appears to differ between rat and cat, as observed by 5-HT immunocytochemistry in single thin sections. In the rat, the vast majority of 5-HT axon varicosities appear to make asymmetrical

or symmetrical contacts mainly with dendrites (Liem *et al.*, 1993; Liem and Copray, 1996), whereas in the cat, only few would show identifiable junctions (Lazarov and Chouchkov, 1995). It is noteworthy that Liem and Copray (1996) were able to use an immunogold postembedding technique to label some of these 5-HT terminals. They could thus demonstrate the storage of 5-HT in large granular dense-core vesicles, as well as in small round or pleomorphic vesicles, as previously inferred from cytochemical, radioautographic and immunocytochemical observations (reviewed in Beaudet and Descarries, 1987).

In the *spinal trigeminal nucleus caudalis*, which corresponds to the dorsal horn of the cervical cord, the densest 5-HT innervation is that of lamina I (Li *et al.*, 1997; López Costa *et al.*, 1994), in which nociceptive primary afferents make synapses. As in the dorsal horn of spinal cord (see below), a majority of 5-HT varicosities in this region do not make synapses, as visualized with 5-HT immuno-electron microscopy in single thin sections (Li *et al.*, 1997; López Costa *et al.*, 1994). Some, however, display symmetrical junctions onto neuronal somadendrites that may be retrogradely labeled with lectin wheatgerm agglutinin conjugated to horseradish peroxidase (WGA-HRP) from the parabrachial or thalamic region (Li *et al.*, 1997). These synaptic contacts are then mostly found on dendritic profiles, occasionally on somata and rarely on dendritic spines. Because 5-HT<sub>1</sub> and 5-HT<sub>3</sub> receptors are known to be present on primary afferent axons of the dorsal horn (Daval *et al.*, 1987; Hamon *et al.*, 1989), but no axo-axonal synaptic contacts are made by its 5-HT afferents, it is likely that diffuse 5-HT transmission controls the release of neurotransmitters from these as well as the spinal cord nociceptive afferents (Li *et al.*, 1997).

In the rat *motor trigeminal nucleus*, the density of 5-HT innervation has been estimated at  $1.8 \times 10^6$  varicosities per mm<sup>3</sup> of tissue (Schaffar *et al.*, 1984). At the electron-microscopic level, it has been suggested that, in both rat and cat, 5-HT neurotransmission might be only partially synaptic, as many [<sup>3</sup>H]5-HT-labeled or 5-HT immunoreactive axon varicosities failed to show a synaptic junction in single thin sections (Schaffar *et al.*, 1984; Nagase *et al.*, 1997). However, in a discordant report, Saha *et al.* (1991) claimed that virtually all 5-HT axon terminals in the motor trigeminal nucleus of rat were endowed with a synaptic junction. Both symmetrical and asymmetrical synaptic contacts, mostly made with dendritic shafts, were observed in each of these studies.

### ***Facial motor nucleus***

The facial motor nucleus receives a prominent 5-HT innervation, as demonstrated by fluorescence histochemistry

(Fuxe, 1965) and biochemical measures (Palkovits *et al.*, 1974). In a radioautographic study of this nucleus after [<sup>3</sup>H]5-HT uptake *in vivo*, Aghajanian and McCall (1980) demonstrated the existence of axo-somatic and axo-dendritic synapses formed by 5-HT axon varicosities and reported a synaptic incidence of 19 percent in single thin sections. This suggested that many of these terminals were synaptic, providing a morphological substrate for the facilitatory effects of 5-HT on the activity of motoneurons (McCall and Aghajanian, 1979).

### *Ambiguous nucleus*

In a 5-HT immunocytochemical study, the ambiguous nucleus of *Macaca fuscata* was examined at the electron-microscopic level. Takeuchi *et al.* (1983) confirmed the existence of synapses, both symmetrical and asymmetrical, made by 5-HT terminals on cell bodies and dendrites of motoneurons in this nucleus, as well as in the motor trigeminal, facial and accessory nerves, and hypoglossal nuclei.

### *Nucleus of the solitary tract*

The nucleus of the solitary tract is an important relay in processing respiratory and cardiovascular inputs to the central nervous system. This region contains a high level of endogenous 5-HT (Palkovits *et al.*, 1974), and its 5-HT innervation has been reported to be moderately dense, as visualized by fluorescence or light microscopy after immunocytochemical labeling (Fuxe, 1965; Steinbusch, 1981; Maley and Elde, 1982; Pickel *et al.*, 1984). Electron-microscopic studies in this nucleus have been conducted in the rat (Pickel *et al.*, 1984; Huang and Pickel, 2002; Huang *et al.*, 2004) and cat (Elde *et al.*, 1982; Maley and Elde, 1982; Maley *et al.*, 1990). After [<sup>3</sup>H]5-HT uptake in rat, 30 percent of the single thin section profiles of labeled varicosities displayed a synaptic specialization. Symmetrical as well as asymmetrical synapses on either dendritic branches or spines were also observed (Pickel *et al.*, 1984). Combined radioautography and immunocytochemistry allowed the visualization of synaptic contacts between 5-HT axon varicosities and tyrosine hydroxylase-immunolabeled dendrites (Pickel *et al.*, 1984), suggesting a prominent role of 5-HT in cardiovascular regulation through synaptic control of noradrenergic neurons innervating the hypothalamus.

Studies of the subcellular distribution of 5-HT<sub>2A</sub> and 5-HT<sub>3A</sub> receptors in relation to 5-HT-immunolabeled

terminals have, however, underlined the importance of diffuse transmission in the rat nucleus of the solitary tract to activate receptors at a distance from 5-HT uptake sites (Huang and Pickel, 2002; Huang *et al.*, 2004). In the cat, serial sections analysis has confirmed the lack of synaptic specialization on a vast majority of 5-HT axon varicosities in this nucleus (Maley and Elde, 1982). The rare synaptic contacts that were then observed were asymmetrical and, as in rats, mostly made with dendritic branches or spines.

### *Inferior olivary complex*

All subdivisions of the inferior olivary complex have been shown to receive a 5-HT input, with some degree of inter-species variability (Wiklund *et al.*, 1977; Takeuchi and Sano, 1983b; King *et al.*, 1984). In the rat, the source of this 5-HT innervation has been identified as the nucleus paragigantocellularis, which contains a part of the B3 5-HT group, as already mentioned (Bishop and Ho, 1986). There is strong immunohistochemical evidence for the coexistence of 5-HT and substance P in at least some of these olivary afferents (Paré *et al.*, 1987). In the dorsal accessory olive of rat, 5-HT axon terminals display a very low incidence of synaptic contacts (Wiklund *et al.*, 1981). Less than 5 percent of 750 [<sup>3</sup>H]5-HT labeled profiles examined in single thin sections appeared to be synaptic. In the opossum, a similarly low incidence (2 percent) was observed using either [<sup>3</sup>H]5-HT radioautography or 5-HT immunocytochemistry (King *et al.*, 1984). In both species, 5-HT synapses were mostly asymmetrical and established with dendritic branches. The non-synaptic 5-HT terminals were found in close apposition with dendritic shafts, somatic appendages or spines. In the caudal medial accessory nucleus of the opossum, a substantial number of 5-HT varicosities were observed in close apposition with nerve cell bodies or axon terminals (King *et al.*, 1984).

### *Dorsal column nuclei*

According to the 5-HT immunocytochemical study of Blomqvist and Broman (1993), the 5-HT innervation of the dorsal column nuclei (DCN) is heterogeneously distributed in a pattern faithfully related to the cytoarchitectonic subdivisions of these nuclei in both cats and owl monkeys. In the cat, electron-microscopic examination showed that these 5-HT fibers were thin and unmyelinated, and studded with small varicosities juxtaposed to dendrites, other terminals and cell bodies, but rarely made a synaptic contact.

### 5-HT innervation of the cerebellum

The existence of a 5-HT innervation in the cerebellum was first demonstrated in the rat, with the histochemical fluorescence technique (Hökfelt and Fuxe, 1969). Subsequent 5-HT immunohistochemical studies showed this innervation to be sparse and heterogeneously distributed (Takeuchi *et al.*, 1982). The ultrastructure of this 5-HT innervation has been examined in both the cerebellar cortex and cerebellar nuclei of rat and monkey.

As demonstrated with [<sup>3</sup>H]5-HT uptake radioautography in the *cerebellar cortex* of both species (Chan-Palay, 1975), a small contingent of the cerebellar 5-HT afferents corresponds to mossy fibers confined to the granular layer, whereas the majority belong to a diffuse projection system which arborizes in all three cortical layers (Chan-Palay, 1975; Beaudet and Sotelo, 1981), presumably arising from the brainstem as well as midbrain raphe cell groups (Chan-Palay, 1975). The large mossy fiber 5-HT varicosities typically form numerous asymmetrical synaptic contacts on the dendritic shafts of granule cells (Chan-Palay, 1975; Palay and Chan-Palay, 1976; Beaudet and Descarries, 1981; Beaudet and Sotelo, 1981). A few also make synapses 'en marron' with the dendrites of Golgi cells (Chan-Palay, 1975). In contrast, a very small proportion (<9 percent) of the smaller varicosities of the diffuse system make synaptic junctions (Beaudet and Sotelo, 1981). In single sections from the granular layer, these authors observed only 2 of 75 such terminals in synaptic contact with dendrites of Golgi cells, whereas in the molecular layer they found 2 of 50 such varicosity profiles in synaptic contact with Purkinje cell branchlet spines. In the *cerebellar nuclei*, the 5-HT axons are scarce and their varicosities have been reported to make synaptic contact with the soma of interneurons and the dendrites of large and small projection neurons (Chan-Palay, 1975; see also Chan-Palay, 1977).

Sotelo and Beaudet (1979) examined the 5-HT innervation in the agranular cerebellum of rat after neonatal X-irradiation (see also Beaudet and Sotelo, 1981). Interestingly, in this modified environment only the diffuse 5-HT system developed, and in the adult its varicosities were all found to make synapses with either the branchlet spines of Purkinje cell dendrites or the dendritic shafts of Golgi cells. This finding was interpreted as indicating that the territory of innervation can exert a determinant influence on the synaptic modeling of incoming 5-HT afferents.

### 5-HT innervation of the spinal cord

5-HT axon terminals are present in all laminae of the gray matter of the spinal cord (Fuxe, 1965; Ségu and Calas,

1978; Steinbusch, 1981). These axons mainly originate from the brainstem, namely from the medullary raphe complex and from 5-HT neurons located in the central gray and reticular nuclei of the midbrain (Bowker *et al.*, 1981, 1987). In rat and primates, 5-HT neurons have been visualized within the spinal cord itself (LaMotte *et al.*, 1982; Bowker, 1986a; Newton *et al.*, 1986), and could give rise to a small proportion of spinal 5-HT axon varicosities.

The *dorsal horn* (Rexed's laminae I–IV), and particularly its superficial layers I and II, receive the densest 5-HT innervation (Steinbusch, 1981; LaMotte and De Lanerolle, 1983). The ultrastructural features of these axon terminals have been examined in rat, cat and monkey, using the radioautographic or immunocytochemical approach (Table 1). In both cat and monkey, including the dorsal horn of caudal medulla in cat (Ruda *et al.*, 1981b), most of these 5-HT varicosities were shown to establish symmetrical synaptic contacts with the shaft of either proximal or distal dendrites (Ruda and Gobel, 1980; Ruda *et al.*, 1981a, 1982; LaMotte and De Lanerolle, 1983; Light *et al.*, 1983). Fewer 5-HT varicosities were found to make synapses on neuronal perikarya, but examples of somata contacted by multiple 5-HT endings (pericellular arrangements) were found in cat lamina I (Ruda *et al.*, 1982).

In cat, the morphological heterogeneity of dendrites synaptically contacted by 5-HT terminals led to the suggestion that several types of intrinsic neurons in the dorsal horn received a 5-HT input (Ruda *et al.*, 1982). Within layers I and II of the caudal medulla, membranous appositions and synaptic contacts between [<sup>3</sup>H]5-HT-labeled axons and enkephalin immunoreactive dendrites could be demonstrated, indicating that enkephalin-containing neurons were one of the recipient neuronal types (Glazer and Basbaum, 1984). A number of light-microscopical observations were also made, suggesting that some 5-HT axon varicosities terminate on physiologically identified nociceptive specific cells as well as wide dynamic range neurons projecting to the mesencephalon and thalamus (Hoffert *et al.*, 1983; Miletic *et al.*, 1984; Hylden *et al.*, 1986). In a study of laminae III and IV combining retrograde tracing and 5-HT immunocytochemistry at light- and electron-microscopic levels, nearly all retrogradely labeled neurons which project to the dorsal column nuclei displayed 5-HT terminals apposed to their perikarya or proximal dendrites in both cat and monkey (Nishikawa *et al.*, 1983). Some of these terminals were observed to make symmetrical synaptic contacts, indicating that both wide dynamic range and low threshold mechanoreceptive neurons received 5-HT afferents. Subsequently, in cat, 5-HT terminals were also found on dorsal horn spino-cerebellar tract neurons and dorsal horn interneurons in pathways from muscle afferents identified according to electrophysiological criteria,

as well as on interneurons labeled intracellularly with horseradish peroxidase (Maxwell and Jankowska, 1996; Jankowska *et al.*, 1997). Again, small symmetrical synaptic contacts were infrequently seen on these cell bodies, but more commonly on proximal and intermediate parts of their dendrites.

In the rat, as opposed to cat and monkey, few synaptic differentiations are made by 5-HT endings on either neuronal cell bodies or dendrites of the dorsal horn (Maxwell *et al.*, 1983, 1985; Mizukawa *et al.*, 1986; Marlier *et al.*, 1991, 1992; Ridet *et al.*, 1993; Ridet, 1994). Ridet *et al.* (1993) did examine a large population of these 5-HT terminals in serial thin sections, and estimated their synaptic incidence at 37 percent. In rat, as well as in cat and monkey dorsal horn, it was also noted that 5-HT terminals are often juxtaposed to other nerve endings (Maxwell *et al.*, 1983, 1985; Ruda *et al.*, 1982; LaMotte and De Lanerolle, 1983), suggesting a distal control by 5-HT of the release of other transmitters.

The ultrastructure of 5-HT axon terminals has also been characterized by immuno-electron microscopy in the *intermediolateral cell column* of rat, guinea pig and rabbit (Mizukawa *et al.*, 1986; Chiba and Masuko, 1987; Poulat *et al.*, 1992; Jensen *et al.*, 1995). Some of these nerve endings were then shown to make appositional or synaptic contacts on dendrites and neuronal cell bodies, which were later identified as those of preganglionic sympathetic neurons projecting to the superior cervical ganglion or the adrenal medulla by combining 5-HT immunocytochemistry with retrograde axonal tracing (Vera *et al.*, 1990; Jensen *et al.*, 1995). In rat, 5-HT terminals were also found in close apposition with cell bodies and proximal dendrites of preganglionic sympathetic neurons in the *intermediolateral cell column* or parasympathetic neurons in sacral nuclei that project to the major pelvic ganglion (Ranson *et al.*, 2006). Synaptic junctions were apparently not made by these 5-HT varicosities, whereas 5-HT varicosities in regions surrounding the labeled preganglionic cells could be seen in synaptic contact with unlabeled somata and dendritic processes of presumed interneurons. This was taken as an indication that in rat, the 5-HT modulation of pelvic preganglionic neurons primarily involved indirect connections via local interneurons. It should be noted that coexistence of 5-HT with substance P (SP) and with thyrotropin-releasing hormone (TRH) had been demonstrated by confocal immunofluorescence microscopy in fibers and terminals apposing identified preganglionic sympathetic neurons in the *intermediolateral cell column* of rat (Appel *et al.*, 1986, 1987). Consistent with these observations, the axon terminals visualized by Poulat and colleagues in the *intermediolateral cell column* of rat thoracic spinal cord after single immunocytochemical labeling for either 5-HT, SP or TRH displayed identical

intrinsic and relational ultrastructural features and formed symmetrical and asymmetrical synaptic junctions with dendritic branches in identical proportion, as if belonging to the same neurons.

Since the first fluorescence histochemical demonstration of their existence in rat spinal cord (Fuxe, 1965), several studies have described the ultrastructural characteristics of 5-HT terminals around the large neurons in the *ventral horn* of rat, cat or monkey (Table 1). In all three species, 5-HT immuno-electron microscopic investigations showed that these 5-HT axon terminals synaptically contacted the soma or dendrites of motoneurons (Mizukawa and Takeuchi, 1982; Pecci-Saavedra *et al.*, 1983; Mizukawa *et al.*, 1986). Ridet (1994) subsequently demonstrated in serial thin sections that all 5-HT terminals in this part of the rat spinal cord were synaptic, accounting for the direct excitatory effects of 5-HT on ventral horn neurons described in micro-iontophoretic experiments (White and Neuman, 1980).

In the monkey ventral horn, a multiple fluorescence immunocytochemical study demonstrated that a subpopulation of 5-HT endings was also immunoreactive for substance P or TRH (Bowker, 1986b; Harkness and Brownfield, 1986), suggesting that the three molecules could be released from the same fibers to regulate the activity of motoneurons. An electron-microscopic study of axon terminals singly immunolabeled for 5-HT, SP and THR, carried out in the motor nucleus of spinal cord segments L7–S1 in the adult cat (Ulfhake *et al.*, 1987), described the immunoreactive boutons as preferentially distributed to the proximal dendritic domain of motoneurons, but rarely making a synaptic specialization in single thin sections, again suggesting that many of them might in fact contain the three transmitters. This was also in keeping with an earlier demonstration by Pelletier *et al.* (1981) that, in adjacent thin sections, both 5-HT and substance P immunoreactivity could be found in the same large granular (dense-core) vesicles of some anterior horn terminals.

Immuno-electron microscopic studies of the 5-HT innervation of intracellularly labeled neurons have also been carried out in the phrenic nucleus of cat at the C5 segment level (Holtman *et al.*, 1990; Pilowsky *et al.*, 1990). 5-HT immunoreactive boutons were then frequently found in close apposition or making symmetrical and asymmetrical synaptic contact with phrenic motoneurons, which were more common on dendrites than cell bodies. The ultrastructure of 5-HT immunoreactive terminals in the phrenic nucleus has also been described in some detail by Tai *et al.* (1997), who examined the plasticity of this innervation in the rat 30 days after hemisection at the C2 segment level. It was then shown that a majority of the 5-HT immunoreactive terminals formed axodendritic

contacts, with either asymmetrical or symmetrical junctions onto retrogradely labeled phrenic motoneurons, but axosomatic synapses were also seen. After the hemisection, there was an increased number of 5-HT terminals in the phrenic nucleus, and the total number and length of asymmetrical and symmetrical junctional complexes per 5-HT terminal were significantly greater, as well as the proportion of 5-HT varicosities displaying multiple synapses.

Lastly, in a detailed immunocytochemical study of the 5-HT innervation of alpha-motoneurons in the lumbar spinal cord of adult cats, Alvarez *et al.* (1998) reported that the spatial distribution of 5-HT terminals observed in close contact with proximal and distal dendritic branches at the light-microscopic level essentially matched the distribution of the surface membrane area of these postsynaptic neurons. Moreover, in serial sections for electron microscopy, these authors observed many of these 5-HT varicosities making a synaptic junction, confirming that the bulbospinal 5-HT system does provide a significant direct synaptic input to spinal motoneurons innervating skeletal muscles.

### Concluding remarks

Over the past 40 years, the various methods applicable to the ultrastructural identification of 5-HT neurons in mammalian CNS have yielded an image of these neurons quite distinct from the usual textbook schematization (Figure 3). Whereas some 5-HT axons have been demonstrated to be myelinated in projection pathways, particularly in the monkey (Azmitia and Gannon, 1983, 1986), widespread innervation by fine, unmyelinated axons whose multiple branches bear innumerable varicosities (presumptive release sites) appears to be the rule for most if not all central 5-HT neurons (Descarries *et al.*, 1990). It may also be assumed that such terminal arbors, bearing varicosities that often lack a junctional specialization and therefore lie free in the neuropil, are highly plastic, not only in a functional sense but also in their morphological configuration and relationship with their microenvironment (Descarries *et al.*, 1975; Beaudet and Descarries, 1978). This has already been considered as a determinant of the remarkable capacities of 5-HT neurons for regeneration and re-establishment of function, in contrast to those of more hard-wired CNS systems. The development of cell-imaging techniques for the examination of transmitter-identified axons in live brain should eventually provide definitive evidence of such a plasticity and capacities.

Wherever 5-HT endings make a synapse, double-immunolabeling methods and the combination of immunocytochemistry with other neurocytological methods

already allow for identification of some of the cellular targets of 5-HT neurons in terms of transmitter(s) content, territory of projection, anatomical origin and/or functional properties. However, much remains to be learned about the role and mode of action of 5-HT released from non-synaptic axon varicosities, and which might then reach distant targets by diffusion in the extracellular space. In regions of high innervation density, the existence of a low ambient concentration of 5-HT must also be considered, which could permanently regulate the expression and or functional state of high-affinity receptor subtypes for 5-HT and for other transmitters located either on the 5-HT neurons themselves or on other neuronal types, as well as on glial cells and microvessels (for further discussion, see Descarries and Mechawar, 2000).

Current information on the ultrastructural localization of the 14 subtypes of 5-HT receptors thus far characterized in the mammalian CNS is still fragmentary (for review, see Descarries *et al.*, 2006). When the electron-microscopic visualization of one or the other of these receptors will be combined with that of 5-HT terminals, the morphological observations at the ultrastructural level will assume even greater functional significance. Further knowledge of the regional density and ultrastructural features of the 5-HT innervation and of the cellular and subcellular localization of 5-HT receptors should also help in achieving a more reliable interpretation of brain-imaging data soon to come regarding the regional distribution of the SERT and of the various 5-HT receptors in live animal or human brain, and health, disease or therapeutic states.

### Acknowledgements

Personal studies referred to in the text were funded in large part by grants to Laurent Descarries from the former Medical Research Council of Canada and current Canadian Institutes of Health Research. Martin Parent was the recipient of a Herbert H. Jasper Fellowship from the Groupe de recherche sur le système nerveux central (GRSNC), and of a postdoctoral fellowship from the Fonds de la recherche en santé du Québec (FRSQ). The FRSQ also provided infrastructure support (GRSNC) to the authors' work. The authors also thank Claude Gauthier for his help in the preparation of Figure 3.

# Classification and Signaling Characteristics of 5-HT Receptors

Joël Bockaert\*, Sylvie Claeysen, Aline Dumuis and Philippe Marin

*Institut de Génomique Fonctionnelle, Université de Montpellier, CNRS UMR 5203, INSERM U661, Montpellier, France*

**Abstract:** Serotonin (5-hydroxytryptamine; 5-HT), along with its receptors, is one of the oldest molecular devices assuming intercellular communication, being present as soon as simple nervous systems appeared during evolution. 5-HT receptors (7 classes, 5-HT<sub>1</sub> to 5-HT<sub>7</sub>, coded by 17 different genes) are G protein-coupled receptors (GPCR) except for 5-HT<sub>3</sub> receptors, which are ionic channels. Splicing and editing add to the diversity of 5-HT receptors. They were first defined on a pharmacological basis and then on a gene structural basis, but the concordance between these two classifications is remarkable. The complexity of signaling events, including G protein-independent signaling of the GPCR classes, is not yet fully understood, and underscores the physiological importance of 5-HT. 5-HT receptors are associated with a large number of proteins involved in their localization, traffic and the fine-tuning signaling. Homodimerization and heterodimerization of 5-HT receptors with other GPCRs but also ligand-directed signaling (signaling dependent on the ligand and not only on the receptor) add to the complexity. Finally, 5-HT receptors are the targets of many therapeutic drugs on the market, in development and yet to be developed.

**Keywords:** serotonin, 5-hydroxytryptamine, 5-HT, G protein-coupled receptors, GPCR, signaling, G protein, G protein-associated proteins, GIPs, pharmacology.

## Introduction

G protein-coupled receptors (GPCRs) are certainly among the oldest devices devoted to signal transduction, being present before plants, fungi and animal. Fungi (for example, *Saccharomyces cerevisiae*) express pheromone- and glucose-sensing GPCRs (for further reading, see Bockaert and Pin, 1999; Fredriksson *et al.*, 2003; Bockaert *et al.*, 2005). Although serotonin (5-hydroxytryptamine, 5-HT) is also one of the oldest cell–cell communication signaling molecules, it seems that both serotonin and associated receptors did not appear before the emergence of excitable cells and simple nervous systems such as those of coelenterates (Cnidaria) (Hajj-Ali and Anctil, 1997), tunicates, nematodes, mollusks and insects (Kroeze and Roth, 2006). Once present, 5-HT receptors were ‘tinkered’ with to generate a large diversity of molecules, probably to ensure a fine control of intracellular signaling and cellular functions. Indeed, there are at least seven subclasses of 5-HT receptors in the nematode *Caenorhabditis elegans*

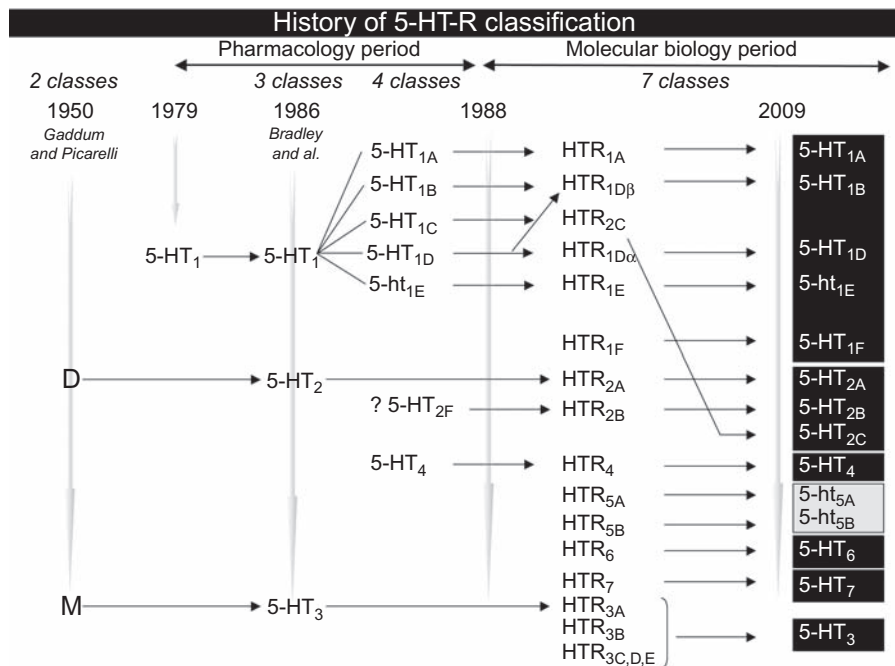

and four in *Aplysia*, *Drosophila*, and *Anopheles* mosquitoes (Kroeze and Roth, 2006).

The classification of 5-HT receptors can be based on both their primary sequence dendrograms (trees based on sequence alignments) and/or their pharmacology. The pharmacology of invertebrate 5-HT receptors is rather poor for obvious reasons (compounds are not developed by the pharmaceutical industry), and only sequence characteristics can be used for classification. The dendrograms show few discrete groupings for invertebrate GPCRs, apart from one for 5-HT<sub>7</sub>-like receptors (Kroeze and Roth, 2006). Thus, the classification of invertebrate 5-HT receptors is almost non-existent.

In vertebrates, the classification has followed a slow evolution over the past 50 years. Two main periods can be distinguished: a pharmacological period, during which the development of specific 5-HT ligands permitted a fairly good classification, and a molecular period in which the cloning of 5-HT receptors completed the pharmacological classification. It is interesting to note that an excellent match was found between the two (Figure 1). The pharmacological period defined four classes (5-HT<sub>1–4</sub>), and the molecular cloning period three more (5-HT<sub>5–7</sub>). Some

**Figure 1** Historical perspective of 5-HT-R classification. Scientists interested in 5-HT receptors know that Gaddum and Picarelli proposed the first classification. Using binding studies and functional studies (generally cAMP production), 8 receptors were ‘pharmacologically’ characterized. Finally, during the ‘molecular biology’ period 13 different genes coding 5-HT receptors were cloned. There is a remarkable concordance between the pharmacological classification and the classification based on gene identification. The only major discrepancy was the 5-HT<sub>2C</sub> receptor, which was named 5-HT<sub>1C</sub> during the pharmacological period.

subclasses have also been defined by molecular biology. The actual dendrogram of vertebrate 5-HT receptors shows groupings that fit with the classification defined by pharmacology (binding site structure). The historical evolution of the 5-HT receptor classification will be reviewed here, and we will also show that not only the coding sequences but also the intron/exon structure of the 5-HT receptor genes can be classified into seven classes.

It is evident that the point of having so many receptors is *not* just to allow development of specific and therapeutic drugs by the pharmaceutical industry. The point, in a physiological and evolutionary perspective, is that these receptors have different cellular expression and control differently, via different fine signaling events, cell physiology. Indeed, each receptor subclass has a different signaling repertoire. The classical signaling events associated with most of these receptors have been reviewed (Bockaert *et al.*, 2006; Hannon and Hoyer, 2008). We will update these data, insisting on the new concepts and data showing that knowledge of the complexity of signaling cascades of 5-HT receptor classes and subclasses is still in its infancy.

The different drugs and radioligands characterizing each receptor are not presented systematically here, since this has recently been well done (Hannon and Hoyer, 2008).

### Historical perspective of 5-HT receptor classification: a ping-pong game between pharmacology and molecular biology

As already stated, there have been two main periods of classification; pharmacological and molecular biology.

#### The four pharmacologically defined 5-HT receptor classes

The pharmacological period obviously started in 1950 when Gaddum and colleagues (Gaddum and Picarelli, 1957) found that, in the guinea pig ileum, the 5-HT-induced contracting effect could be blocked in part by dibenziline (the D receptor, which was finally characterized as a postsynaptic 5-HT<sub>2</sub> receptor) and in part by morphine (the M receptor, which was finally characterized as a presynaptic 5-HT<sub>3</sub> receptor).

Between 1975 and 1980, great efforts were made by Fillion in France (Fillion *et al.*, 1976) and Peroutka and Snyder in the USA (Peroutka and Snyder, 1979) to use radiolabeled [<sup>3</sup>H]-5-HT, [<sup>3</sup>H]-LSD and [<sup>3</sup>H]-spiperone a dopamine/5-HT antagonist to label brain 5-HT receptors. Two types of receptors were pharmacologically characterized with these binding studies; 5-HT<sub>1</sub> (labeled with

[<sup>3</sup>H]-5-HT and [<sup>3</sup>H]-LSD) and 5-HT<sub>2</sub> receptors (labeled with [<sup>3</sup>H]-spiperone and [<sup>3</sup>H]-LSD). Based on both data from Gaddum and colleagues and binding data, Bradley and co-workers (Bradley *et al.*, 1986) proposed the existence of three 5-HT receptor families, 5-HT<sub>1</sub>, 5-HT<sub>2</sub> and 5-HT<sub>3</sub>, the latter being only based, at that time, on the existence of the Gaddum 'M' response. It is remarkable that even after 20 years of intensive discovery of new 5-HT receptor ligands and intensive molecular cloning, the 3 classes remain pharmacologically the same.

In addition to binding studies and organ responses (such as guinea-pig contractions) another tool was introduced in the 1980s: the use of second messenger production in intact cells or membranes following 5-HT stimulation. This tool was superb for studying structure–response relationships, and had the advantage of clearly distinguishing agonists from antagonists. It was at this time that we discovered the 5-HT<sub>4</sub> receptor which was able to stimulate cAMP production in colliculi neurons (Dumuis *et al.*, 1988a; Bockaert *et al.*, 2008).

### ***Pharmacologically defined 5-HT<sub>1</sub> and 5-HT<sub>2</sub> sub-classes***

Before molecular cloning began, binding studies (using more and more selective radio-ligands) and second messenger studies were used to characterize the subtypes of 5-HT<sub>1</sub> receptors.

5-HT<sub>1A</sub> was first characterized using [<sup>3</sup>H]-8-OH-DPAT (Gozlan *et al.*, 1983), and corresponds to the spiperone sensitive [<sup>3</sup>H]-5-HT binding sites (Pedigo *et al.*, 1981). A few years later this receptor was found, in neurons, to be negatively coupled to adenylyl-cyclase (De Vivo and Maayani, 1986; Weiss *et al.*, 1986).

5-HT<sub>1B</sub> was first characterized as the part of the [<sup>3</sup>H]-5-HT binding sites insensitive to spiperone and 8-OH-DPAT, and then as binding sites labeled with [<sup>125</sup>I]-CYP (cyanopindolol). We found that this presynaptic receptor was negatively coupled to adenylyl cyclase in substantia nigra (Bouhelal *et al.*, 1988).

5-HT<sub>1C</sub> had a very transient existence in the 5-HT<sub>1</sub> class. This receptor, found at high density in the choroid plexus and labeled with [<sup>3</sup>H]-5-HT (as with other 5-HT<sub>1</sub> receptors) but coupled to inositol phosphate production and Ca<sup>2+</sup> signaling (as with 5-HT<sub>2</sub> receptors), definitively joined the 5-HT<sub>2</sub> family following its early cloning, its sequence homology with other 5-HT<sub>2</sub> receptors and an obvious 5-HT<sub>2</sub> pharmacology (Hannon and Hoyer, 2008) (Figure 1).

The history of 5-HT<sub>1D</sub> is even more complex. It was first observed that the [<sup>125</sup>I]-CYP ligand, which binds to 5-HT<sub>1B</sub> in rodents, fish and opossum, was not labeling such homolog receptors in guinea-pig, pig and human.

However, a functionally similar receptor (inhibition of 5-HT release; inhibition of adenylyl-cyclase) was present in those species and thus was called 5-HT<sub>1D</sub>. It was the cloning period that shed some light. Indeed, in humans, two genes coding for receptors having a 5-HT<sub>1D</sub> pharmacology were cloned (5-HT<sub>1Dα</sub> and the 5-HT<sub>1Dβ</sub>), having a very slight difference in pharmacology. In rats, too, two genes are present; α and β. Thus, the 5-HT<sub>1Dβ</sub> gene in both rodent and human codes for the now termed 5-HT<sub>1B</sub> receptor (Figure 1). The binding of [<sup>125</sup>I]-CYP ligand to the rodent receptor and not to the human receptor and, more generally, the low affinity of the human receptor for β-blockers is due to a single residue difference in TM7 (an asparagine, N355, in human, and a threonine in rodent) (Adham *et al.*, 1994).

5-HT<sub>1Dα</sub> codes for 5-HT<sub>1D</sub> receptor in both rodents and humans. Selective ligands are now available to distinguish between 5-HT<sub>1B</sub> and <sub>1D</sub> receptors (Hannon and Hoyer, 2008). All active anti-migraine drugs (triptans) act on 5-HT<sub>1B</sub> receptors. Whether or not some may be active via a specific action on 5-HT<sub>1D</sub> receptors is still a matter of debate (Hannon and Hoyer, 2008).

The putative 5-HT<sub>1E</sub> receptor was identified in the human frontal cortex as a residual [<sup>3</sup>H]-5-HT binding when all others 5-HT<sub>1</sub> receptors were blocked. It has not been found in rodents, and no specific drugs are available. A gene has been cloned which codes for a receptor that could correspond to the pharmacologically 5-HT<sub>1E</sub> binding site. Its exact signaling properties remain to be discovered (Hannon and Hoyer, 2008).

When examining the status of 5-HT<sub>2</sub> receptors during the pharmacological period, the actual 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors were clearly defined. 5-HT<sub>2A</sub> was indeed the D receptor of Gaddum (Gaddum and Picarelli, 1957) as well as the 5-HT<sub>2</sub> receptor found in brain by Peroutka and Snyder using binding studies (Peroutka *et al.*, 1981). [<sup>3</sup>H]-Ketanserin rapidly became the reference ligand for 5-HT<sub>2A</sub>. 5-HT<sub>2C</sub> was, in fact, defined as 5-HT<sub>1C</sub> during this period (see above). Both were found to be coupled to phospholipase C. The existence of the actually characterized 5-HT<sub>2B</sub> was 'present' at a subluminal stage during this period. Indeed, a 5-HT<sub>2</sub> receptor was present in the fundus (thus called 5-HT<sub>2F</sub>), in which it induced contraction, but no convincing pharmacological tools were available at that time for its definitive characterization (Hannon and Hoyer, 2008).

### ***The molecular cloning period***

#### ***G-protein-coupled receptors***

The molecular cloning period started with the cloning of the 5-HT<sub>1A</sub> receptor. An orphan receptor (G21) isolated

by cross-hybridization at reduced stringency with a full-length  $\beta_2$ -adrenergic receptor probe appeared to code for the 5-HT<sub>1A</sub> receptor (Fargin *et al.*, 1988). Most of the pharmacologically characterized 5-HT receptors were rapidly cloned (Hannon and Hoyer, 2008), including the fundus receptor first called 5-HT<sub>2F</sub> (for fundus) (Foguet *et al.*, 1992) but later named 5-HT<sub>2B</sub> in view of the existence, at that time, of 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors.

In addition, 'new' genes coding for 5-HT receptors were cloned which were not yet pharmacologically characterized. These included 5-HT<sub>1F</sub>, 5-HT<sub>5A</sub>, 5-HT<sub>5B</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub>.

5-HT<sub>1F</sub> was cloned on the basis of its sequence homology with the 5-HT<sub>1B/1D</sub> receptors (Adham *et al.*, 1993). It is expressed in many brain areas, and has a high affinity for triptans and LSD. It may be a better target for anti-migraine drugs than 5-HT<sub>1B</sub> receptors, since it could be devoid of vasomotor effects. It is negatively coupled to adenylyl-cyclase.

The cloned 5-HT<sub>5A</sub> and 5-HT<sub>5B</sub> proteins (Matthes *et al.*, 1993) have not yet reached the status of 'receptors', since neither their signal transduction nor their physiological function are clearly established.

The 5-HT<sub>6</sub> receptor was suspected to be present in the striatum and some glioblastomes such as NCB20. It was positively coupled with adenylyl cyclase and sensitive to antipsychotic drugs. The cloning was realized in 1993 in the rat (Ruat *et al.*, 1993a). It is essentially present in brain, and is indeed positively coupled to adenylyl cyclase in striatal neurons (Sebben *et al.*, 1994).

Another 5-HT receptor positively coupled with adenylyl cyclase was discovered by homology cloning: the 5-HT<sub>7</sub> receptor (Ruat *et al.*, 1993b). Interestingly, this receptor shares low homology with other members of the 5-HT receptor family (< 50 percent) and high homology with a drosophila 5-HT receptor positively coupled with an adenylate cyclase (> 94 percent) (Kroeze and Roth, 2006).

#### *Ionotropic 5-HT<sub>3</sub> receptors*

This 5-HT receptor is the only one that is not a metabotropic receptor but a ligand-gated ion channel. It is interesting to note that the main neurotransmitters (glutamate, GABA, acetylcholine, 5-HT) have managed, during evolution, to use both rapid (milliseconds) ion-gated channel-mediated and slow (seconds) GPCR-mediated transmission.

Two genes coding for 5-HT<sub>3</sub> receptors have been cloned, 5-HT<sub>3A</sub> (Maricq *et al.*, 1991) and 5-HT<sub>3B</sub> (Dubin *et al.*, 1999; Maricq *et al.*, 1991). They have a high level of identity with other members of the Cys–Cys loop ligand-gated channel superfamily (e.g., nicotinic, GABA-A, glycine receptors), especially in the channel domain area.

The native receptor, as revealed by electron microscopy, is pentameric (Boess *et al.*, 1995). 5-HT<sub>3B</sub> is unable to form a functional receptor on its own; however, it can co-assemble with 5-HT<sub>3A</sub> to form functional 5-HT<sub>3A/B</sub> channels with properties similar to those of native 5-HT<sub>3</sub> receptors. Other human (but not rodent) sequences have been cloned for the 5-HT<sub>3C–E</sub> receptors, but their role as 5-HT<sub>3</sub> receptors is obscured although they can have a modulating role associated with 5-HT<sub>3A</sub> (Niesler *et al.*, 2007; Jensen *et al.*, 2008). Since 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> receptors are co-distributed in the brain as well as in dorsal root ganglia and trigeminal ganglia, hetero-pentameric structures may exist.

#### *Evolutionary consideration*

As seen in Figure 1, the classification proposed during the pharmacological period was, with few exceptions, as discussed in the previous paragraph, confirmed during the molecular cloning period. This indicates that the pharmacologists did a good job in their classification based on structure–function relationships, binding data, and the few elements of signal transduction that were available at that time. In addition, this indicates that the binding sites of all these different receptors co-evolved with the whole primary structure of their corresponding receptors. Indeed, there is a perfect coincidence between the grouping of vertebrate 5-HT receptors as revealed by the dendrogram based on sequence alignments, and classes and sub-classes defined by the pharmacology (Kroeze and Roth, 2006). This was not necessarily expected. Why have such different binding sites to recognize a common neurotransmitter? With the increasing complexity of the neuronal network it was certainly interesting to have an increased diversity of 5-HT receptor signaling (and thus of the receptor domains involved in signaling), as well as a diversity in cellular expression. However, their binding site could have remained similar. Note, however, that the evolution of the binding sites had allowed receptors with different affinity for 5-HT.

Finally, the 5-HT receptor dendrogram shows that the nature of the primary coupling with the G protein is not an element of clustering when considering sequence homologies. The 5-HT<sub>6</sub> receptor coupled to Gs, for example, is more similar to 5-HT<sub>2</sub> receptors coupled to Gq than to 5-HT<sub>7</sub> receptors coupled to Gs.

#### **Genomic, post-genomic characteristics of 5-HT receptors**

5-HTRs are generated from 17 different genes in the human genome (NCBI, Map Viewer at <http://www.ncbi>).

nlm.nih.gov/mapview/); 12 genes encoding metabotropic 5-HT receptors and 5 genes encoding ionotropic 5-HT<sub>3</sub> receptors. There is one pseudogene: 5-HT<sub>5B</sub>.

### Metabotropic 5-HT receptor genes

G-protein-coupled receptor genes diverged from a common ancestor, and their structure reflects their evolutionary relationship (Barnes and Sharp, 1999). 5-HT<sub>1</sub> receptors are coded by intronless genes, and clearly constitute a subgroup of genes that arose by duplication events implicating several chromosomes (1, 3, 5 and 6) (Figure 2). 5-HT<sub>2</sub> receptor genes are also closely related, presenting two similar introns located at the end of transmembrane domain 2 (TM2) and within TM4-coding sequences. The 5-HT<sub>2C</sub> receptor gene presents an additional intron in the extracellular domain of the coding sequences, and extends over more than 183 kb. Alternative splicing of the 5-HT<sub>2</sub> receptor gene does not generate any functional splice variant (Xie *et al.*, 1996). The 5-HT<sub>4</sub> receptor gene is far more complex. The coding sequence extends over more than 185 kb and includes at least 14 exons, leading to multiple splicing combinations. To date, 10 functional splice variants have been described that can be generated by alternative splicing of the human transcript (Bender *et al.*, 2000; Hiroi *et al.*, 2001). For nine of these variants, splicing gives rise to alternate C-terminal domains (Figure 2). As some exons (such as the h or the i exons) do not present any in-frame stop codons, many additional combinations probably remain to be discovered (Brattelid *et al.*, 2004). Indeed, a recent publication described 10 novel splice variants of the porcine 5-HT<sub>4</sub> receptor, including a functional homofusion variant (De Maeyer *et al.*, 2008). The existence of these variants, some of them arising from duplication events, remains to be demonstrated in the human genome. The relevance and the functional role of such a multiplicity of isoforms also remain to be elucidated. The finding that some less well represented 5-HT<sub>4</sub> splice variants (e.g., 5-HT<sub>4(a)</sub> receptor and 5-HT<sub>4(e)</sub> receptor) interact with specific intracellular proteins supports the view that these isoforms are in charge of the fine regulation of signal transduction and are not the result of transcriptional leakage (Joubert *et al.*, 2004). Two 5-HT<sub>5</sub> receptor genes have been described in the rodent, but only the 5-HT<sub>5A</sub> receptor can be generated in humans (Rees *et al.*, 1994). A 5-HT<sub>5B</sub> receptor pseudogene had been localized on chromosome 2 in Build 35.1 of the human genome; however, this annotation has been permanently suppressed in the actual build (36.3) because of insufficient evidence that this locus could be transcribed. The 5-HT<sub>6</sub> receptor gene presents two splicing sites: the first lies in the middle of the intracellular loop 3 and is similar to the splicing site found

in the 5-HT<sub>5A</sub> receptor gene; the second separates exons encoding TM6 and TM7 (Figure 2). A non-functional splice variant has been described for this receptor (Olsen *et al.*, 1999). The human 5-HT<sub>7</sub> receptor gene is more complex: different acceptor and donor sites can be used to generate three receptors that differ in the composition and length of their C-terminal domains (5-HT<sub>7(a)</sub>, 5-HT<sub>7(b)</sub>, and 5-HT<sub>7(d)</sub>). Because of its altered intron–exon organization, the rat gene generates the 5-HT<sub>7(c)</sub> but not the 5-HT<sub>7(d)</sub> isoform (Heidmann *et al.*, 1997). This splicing position giving rise to alternate C-terminuses is similar to that found in the 5-HT<sub>4R</sub> gene. The different C-terminal domains of the 5-HT<sub>7</sub> receptor variants can probably recruit specific sets of intracellular proteins that might modulate their function as demonstrated for the 5-HT<sub>4</sub> receptor isoforms.

### Ionotropic 5-HT<sub>3</sub> receptor genes

The subunits of the pentameric 5-HT<sub>3</sub> ion channel are encoded by five different genes (Barnes *et al.*, 2009; see also Figure 2). HTR3A and HTR3B genes arose by duplication in the same locus (11q23.1). Other duplication events generated multiple copies of the 5-HT<sub>3</sub> receptor gene in the 3q27.1 locus, generating the HTR3C, HTR3D and HTR3E genes, and even a pseudogene (htr3c2). With the exception of HTR3D, all genes presented a common structure of eight to nine exons, the TM regions being encoded by the two to three last exons. An alternative splicing site in the HTR3A gene generates two splice variants of 510 and 478 amino acids (annotated respectively 5-HT<sub>3A(a)</sub> and 5-HT<sub>3A(b)</sub> in the NCBI Gene Database) which differ in TM3 and intracellular loop 3 (Belelli *et al.*, 1995; Miyake *et al.*, 1995; see also Figure 2). The number of 5-HT<sub>3A</sub> receptor isoforms is not fixed to date, as additional splice variants have been reported (Bruss *et al.*, 2000). The HTR3D gene has been described as encoding a 4TM-subunit of 279 residues, lacking the major part of the large N-terminal domain (Niesler *et al.*, 2007; see also Figure 2). However, two alternative transcripts of this gene have been reported that could produce proteins of 454 or 233 amino acids (see accession numbers Q70Z44-1 and Q70Z44-3 in the Uniprot Database, <http://www.uniprot.org>). Further work remains to be done to conclude the relevance of this observation.

### Editing

RNA editing is a dynamic mechanism that generates molecular and functional diversity. The most common type of RNA editing involves nucleotide substitution that consists of either cytidine to uridine (C to U) or, most frequently,

Gene	Gene structure	Gene products	Cds
<b>HTR1A</b> 5q11.2-q13		5-HT <sub>1A</sub> : 422aa	1269b
<b>HTR1B</b> 6q13		5-HT <sub>1B</sub> : 390aa	1173b

**Figure 2** Human gene structures of 5-HT receptor coding sequences. This figure was generated using released data of the human genome project available on the NCBI site (<http://www.ncbi.nlm.nih.gov>) using Map Viewer interface, Gene Database and Consensus CDS Database. Builds 36.2–36.3 were used to localize the exons, except for HTR5B which was only annotated on build 35. The first column presents gene names and cytogenetic localizations. The second column schematizes the exon composition of the coding sequences and the part of the receptor encoded by each exon: open boxes, exons, bridges, splicing events, black boxes, transmembrane domains, curved lines, loops or N- or C-terminal domains. Colors indicate alternative exons and the receptor part encoded in the splice variants. The third column indicates the name and size of the gene products and splice variants (aa, amino acids). The fourth column presents size of the complete coding sequence on the human genome (b, bases; kb, kilobases). To see the full color version of this figure please refer to the color plate at the back of the book. Copies produced via our print on demand service do not contain color plates; if your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

adenosine to inosine (A to I). Inosine is read as guanosine by the translational machinery of the cell (Higuchi *et al.*, 1993). The 5HT<sub>2C</sub> receptor is the only known GPCR to be regulated by editing. Editing takes place at four major positions on exon V (corresponding to the second exon in the coding sequence), termed sites A, B, C and D, and one minor site, termed E. 5-HT<sub>2C</sub> receptor mRNA editing has been identified as A to I discrepancies between genomic and cDNA sequences in the region encoding the second intracellular loop of the receptor. This A to I substitution alters the coding potentials of three codons. Theoretically, 5-HT<sub>2C</sub> receptor editing can generate up to 32 different mRNAs that encode 24 receptor isoforms from the non-edited form (INI) to the fully edited form (VGV) (Fitzgerald *et al.*, 1999). The editing of 5-HT<sub>2C</sub> transcripts is tissue-specific. Seven major 5-HT<sub>2C</sub> receptor isoforms, encoded by 11 distinct RNA species, are expressed in rat brain, compared with 14 receptor isoforms encoded by 23 transcripts in human brain. The most prevalent isoform in human brain is 5-HT<sub>2C</sub>-VSV, whereas 5-HT<sub>2C</sub>-VNV is the most abundant in the rat. Editing is regulated by 5-HT itself. Depletion of 5-HT increases the expression of forms having a high affinity for 5-HT, whereas stimulation of 5-HT<sub>2C</sub> receptors has the opposite effect (Gurevich *et al.*, 2002a). Altered RNA editing of the 5-HT<sub>2C</sub> receptor may play a role in depression. 5-HT<sub>2C</sub> receptor mRNA isoforms expressed in human prefrontal cortex differ in tissues obtained from depressed suicide victims compared with healthy controls. In suicide patients, three abundant isoforms, resulting from an increase at the E and C sites and a decrease at the D site and encoding receptors, are expressed. These isoforms exhibit decreased basal activity and decreased agonist affinity and potency (Gurevich *et al.*, 2002b).

Recently, it has been reported that the small nucleolar RNA (snoRNA) HBII-52, which exhibits sequence complementarity to the alternative spliced exon V encoding for a functional 5-HT<sub>2C</sub> receptor, regulates receptor mRNA splicing. Notably, Prader-Willy syndrome patients (characterized by neonatal muscular hypotonia, early childhood obesity, hypogonadism and mental retardation) who do not express HBII-52 snoRNA exhibit abnormally low levels of the non-edited 5-HT<sub>2C</sub> receptor.

## G protein-mediated signaling

The pleiotropic functions of 5-HT are not only exerted by concerted actions of multiple receptor subtypes, splicing and editing, but also by multiple coupling of each receptor species. Since we have written two recent reviews (Bockaert *et al.*, 2006; Millan *et al.*, 2008) on the subject, we will focus here on the more recent and original aspects

of this important question. In addition, we will try to make the distinction between signaling events established in native cells versus those observed when the receptor is expressed in cell lines.

### 5-HT<sub>1A</sub> receptor

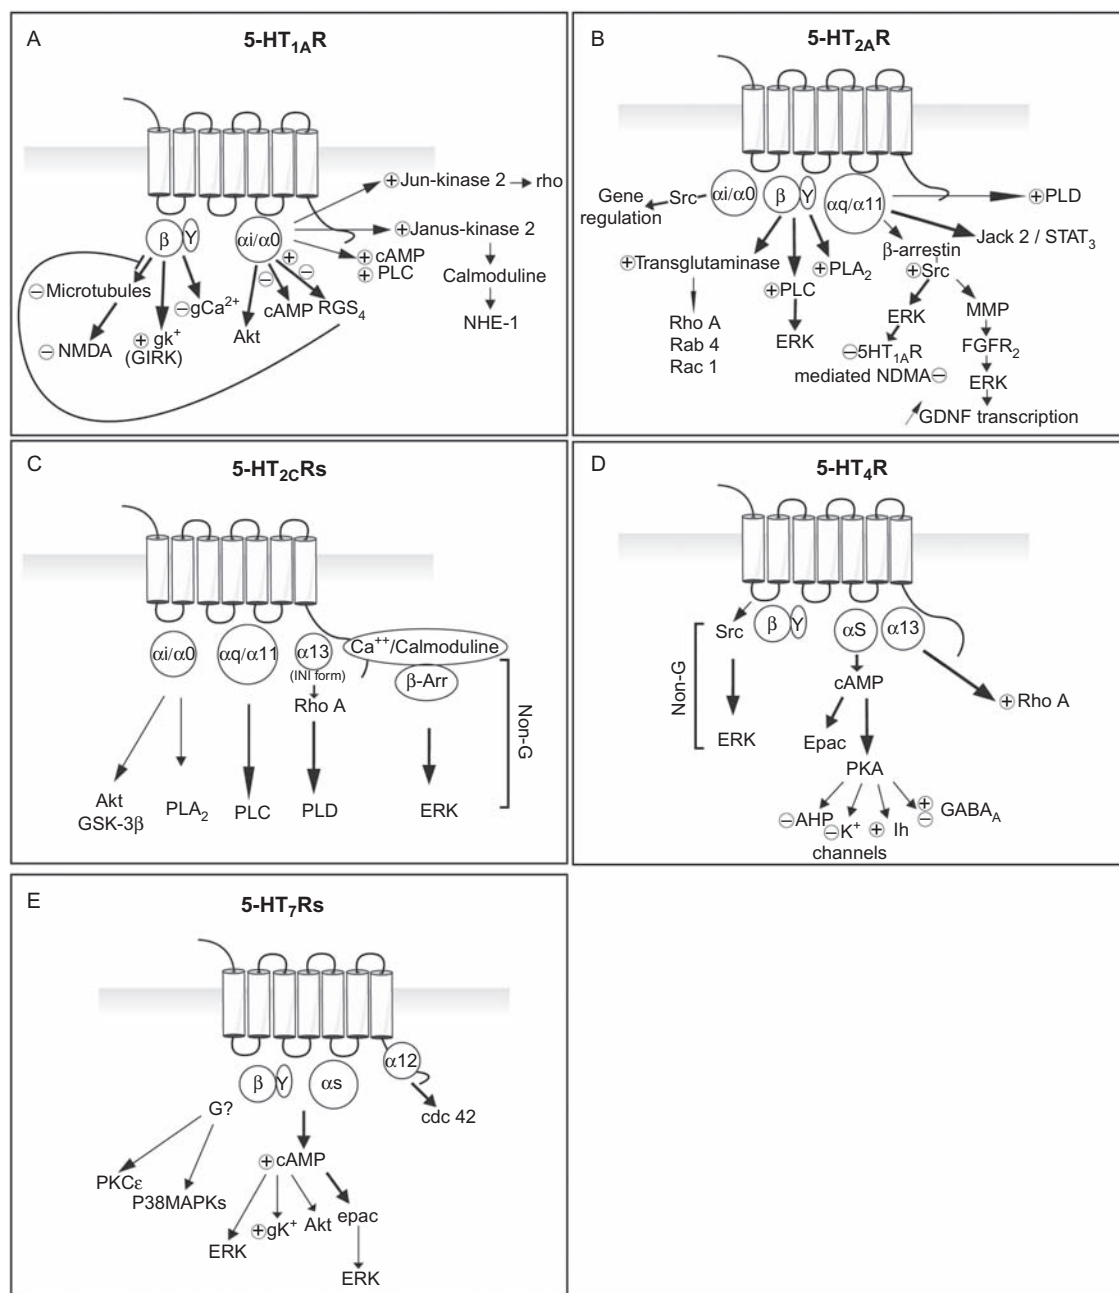

This is an inhibitory receptor coupled to Gi/Go inhibiting the adenylyl-cyclase but also opening G-protein-gated inwardly rectifying gK<sup>+</sup> (GIRK) and inhibiting gCa<sup>2+</sup> (Figure 3A). Interestingly, 5-HT<sub>1A</sub> receptors have different properties depending on their localization on 5-HT neurons (auto-receptors) versus on postsynaptic heterologous neurons. In particular, drugs have different efficacies, and the auto-receptors have a much greater ability to desensitize. The reasons are still obscure, but one possibility may be that autoreceptors are preferentially coupled to Gi<sub>3</sub> and postsynaptic receptors to Go (Mannoury la Cour *et al.*, 2006). Other signaling events mediated through activation of Gi/Go in native tissues (and in some cases *in vivo*) include: (1) activation or inhibition of ERK (extracellular signal-regulated kinase), depending on the brain area (Crane *et al.*, 2007); (2) activation of the Akt pathway (Cowen *et al.*, 2005); and (3) inhibition of NMDA transmission in prefrontal cortex, an effect potentiated by dampening RGS4 function (Gu *et al.*, 2007). RGS4 is an RGS gene associated with schizophrenia (Gu *et al.*, 2007). In COS7 cells, 5-HT<sub>1A</sub> receptors also stimulate both an ERK-dependent anti-apoptotic pathway and a Janus-kinase 2 (Jak2)-dependent pro-apoptotic pathway as well as c-jun N-terminal kinase (Turner *et al.*, 2007a, 2007b).

### 5-HT<sub>1B/1D/1E/1F</sub> receptors

5-HT<sub>1B</sub> receptors are negatively coupled to adenylyl-cyclase via Gi/Go in substantia nigra (Bouhelal *et al.*, 1988; Hamblin and Metcalf, 1991). In transfected cells, 5-HT<sub>1B</sub> receptors regulate PLC, PLD, Akt kinase, neuronal nitric oxide synthase (nNOS), and the ERK pathway. They also activate K<sup>+</sup> channels and inhibit Ca<sup>2+</sup> channels. The negative coupling of 5-HT<sub>1D/1E/1F</sub> receptors to adenylyl-cyclase has only been demonstrated in transfected cells, but likely occurs *in vivo* (Bockaert *et al.*, 2006).

### 5-HT<sub>2A</sub> receptors

5-HT<sub>2A</sub> receptors activate PLC, PLA2 and the ERK pathway (downstream of PLC) in neurons (Bockaert *et al.*, 2006; Figure 3B). Recently, an original signaling pathway has been associated with 5-HT<sub>2A</sub> receptor stimulation

**Figure 3** Signaling pathways of major 5-HT receptors. Heavy arrows indicate the signaling pathways demonstrated in native cells, the others being described in heterologous cells.

in platelets and a rat cortical cell line: the covalent link of serotonin to a glutamine residue of small G proteins such as RhoA and Rab4 as well as Rac1, a process which renders them constitutively active (Walther *et al.*, 2003; Dai *et al.*, 2008). Physical interaction of 5-HT-bound, activated Rab4 (Rab4-GTP) with the serotonin transporter (SERT) has been found to 'paralyze' its translocation from intra-cellular compartments to the plasma membrane (Ahmed *et al.*, 2008). 5-HT<sub>2A</sub> receptors inhibit the 5-HT<sub>1A</sub>-mediated

modulation of NMDA current in pyramidal neurons via an arrestin/Src/ERK pathway (Yuen *et al.*, 2008). In C6 glioma cells, 5-HT<sub>2A</sub> activates matrix metalloproteinases (MMPs) via the Src pathway, the release of FGF receptor 2 ligand, the activation of FGFR2 receptor, the activation of downstream ERK and transcription of GDNF (Tsuchioka *et al.*, 2008). Thus, 5-HT<sub>2A</sub> receptors activate ERK through several pathways. They also activate the Janus kinase-2 (Jak2/STAT) transcription pathway in skeletal and smooth

muscles (Guillet-Deniau *et al.*, 1997; Banes *et al.*, 2005) and PLD in non-neuronal cells.

### 5-HT<sub>2B</sub> receptors

Similarly to 5-HT<sub>2A</sub> receptors, 5-HT<sub>2B</sub> receptors are coupled to Gq/G11 proteins and activate PLC. However, to date, no study has reported such a coupling within neurons. 5-HT<sub>2B</sub> receptors have also been reported to stimulate Ca<sup>2+</sup> mobilization in astrocytes derived from various rat cerebral regions. Additional 5-HT<sub>2B</sub> receptor-mediated signaling pathways have been described in non-neuronal cells expressing endogenous receptors. Stimulation of 5-HT<sub>2B</sub> receptors is associated with an increase in cyclic GMP through the dual activation of constitutive and inducible NOS. Gq/11-coupled 5-HT<sub>2B</sub> receptors also activate PI3K/Akt and ERK1/2 signaling pathways (Bockaert *et al.*, 2006).

### 5-HT<sub>2C</sub> receptors

5-HT<sub>2C</sub> receptors have been reported to activate PLC via Gq/11 in many brain regions, including the choroid plexus (Sanders-Bush and Breeding, 1988; Figure 3C). The non-edited form (5-HT<sub>2CINI</sub>) is more potent in stimulating PLC, and exhibits higher constitutive activity than the edited forms (Niswender *et al.*, 1999). Moreover, 5-HT<sub>2CINI</sub> receptors are capable of coupling to the G13 protein, activating PLD signaling pathway and increasing Rho GTPase activity (McGrew *et al.*, 2002), whereas the fully edited isoform (5-HT<sub>2CVGV</sub>) fails to activate G13. RNA editing has an important implication for signal transduction *in vivo* (Price *et al.*, 2001).

In CHO cells, 5-HT<sub>2C</sub> receptors also activate Gi/Go, modulating PLA2 and Akt/GSK3- $\beta$  (Cussac *et al.*, 2002).

### 5-HT<sub>4</sub> receptors

Since 5-HT<sub>4</sub> receptor was discovered from its capacity to activate adenylyl cyclase, the 5-HT<sub>4</sub>Rs mediated Gs/cAMP/PKA signaling pathway is obviously the best characterized (Figure 3D). In transfected cell lines other couplings have been found, including coupling to Gq and G13 (Bockaert *et al.*, 2006, 2008). Following PKA activation, a series of ionic currents are modulated. These include a long-lasting inhibition of K<sup>+</sup> currents (mediated by a PKA-dependent inhibition of phosphatases), which enhances neuronal excitability, and a decrease in spike accommodation (Ansanay *et al.*, 1995), inhibition of AHP, activation of I<sub>H</sub>, and activation or inhibition of

GABA<sub>A</sub> receptor (Bockaert *et al.*, 2006, 2008). cAMP produced upon 5-HT<sub>4</sub> receptor activation also stimulates the exchange factor Epac, which activates  $\alpha$ -secretase and the release of sAPP $\alpha$  (amyloid precursor protein) via an Epac/Rap1/Ras pathway (Lezoualc'h and Robert, 2003).

### 5-HT<sub>5</sub> receptor

The signaling pathways associated with 5-HT<sub>5</sub> putative receptors are still obscure. No data are available in native cells (Hannon and Hoyer, 2008).

### 5-HT<sub>6</sub> receptors

Like 5-HT<sub>4</sub> receptors and 5-HT<sub>7</sub> receptors, 5-HT<sub>6</sub> receptors are positively coupled to adenylyl-cyclase in neurons (Sebben *et al.*, 1994). 5-HT<sub>6</sub> receptors also activate the ERK pathway in CHO cells via a mechanism partially dependent on PKA and requiring the tyrosine kinase Fyn (Yun *et al.*, 2007).

### 5-HT<sub>7</sub> receptors

The coupling of 5-HT<sub>7</sub> receptors is more documented than that of the 5-HT<sub>6</sub> receptor (Figure 3E). The 5-HT<sub>7</sub> receptor has been recognized as the receptor coupled to adenylyl cyclase exhibiting a high affinity for 5-carboxamidotryptamine (5-CT) in the guinea-pig hippocampus (Shenker *et al.*, 1987; Dumuis *et al.*, 1988b). 5-HT<sub>7</sub> receptors also engage the ERK1/2 pathway in hippocampal neurons via activation of Epac (Lin *et al.*, 2003). Activation of ERK via PKA is also possible. 5-HT<sub>7</sub> receptor activation increases neurite length through a G $\alpha$ 12/RhoA/Cdc42 signaling pathway in hippocampal neurons (Lin *et al.*, 2003; Kvachnina *et al.*, 2005). In astrocytoma cells, 5-HT<sub>7</sub> receptors activate p38 and PKC $\epsilon$ . The implication of G proteins in this pathway is not demonstrated (Lieb *et al.*, 2005).

### Non-G-protein dependent signaling

Recently, many GPCRs have also been shown to signal without activation of G proteins. This non-G-protein mediated signaling generally implicates interactions with GPCR interacting proteins (Bockaert *et al.*, 2004). A classic non-G signaling pathway, which implicates  $\beta$ -arrestins, is the ERK pathway. Long-lasting activation (>5 minutes up to several hours) of ERK induced by many GPCRs, including  $\beta$ -adrenergic receptors or AT<sub>1A</sub>

angiotensin II receptors, is due to their co-internalization with  $\beta$ -arrestin after their uncoupling from G proteins, and takes place in the cytosol. Internalized GPCR- $\beta$ -arrestin complex recruits many proteins, including the Src-Raf-MEK-ERK module. This contrasts with the rapid ( $<5$  min) activation of ERK evoked by GPCRs, which is generally G-protein-dependent and leads to nuclear translocation of ERK. However, several GPCRs, including 5-HT receptors, differ from this general scheme. For instance, both early and sustained phases of ERK activation mediated by the 5-HT<sub>2C</sub> receptor are independent of the receptor's cognate G proteins (Gq, G13 and Gi/o) and require physical interaction of calmodulin with the receptor C-terminal domain, and  $\beta$ -arrestin1 and 2 recruitment by the receptor (Labasque *et al.*, 2008) (Figure 3C). This non-G signaling pathway, established not only in transfected HEK-293 cells but also in cortical neurons and choroid plexus epithelial cells expressing native 5-HT<sub>2C</sub> receptor, might be involved in neurogenesis induced by chronic treatment with 5-HT<sub>2C</sub> receptor agonists and their antidepressant-like activity. Activation of 5-HT<sub>4</sub> receptors likewise induces a sustained ERK phosphorylation in both transfected HEK-293 cells and cultured colliculi neurons (Barthet *et al.*, 2007). Again, this activation was mostly Gs/cAMP/PKA-independent and did not involve any other G proteins (Gq, Gi, Go) and associated downstream messengers. Interestingly, 5-HT<sub>4</sub> receptor-mediated ERK activation did not involve  $\beta$ -arrestins but was dependent on Src tyrosine kinase. This receptor-operated pathway might be important for 5-HT<sub>4</sub> receptor-mediated long-term potentiation (LTP) (Huang and Kandel, 2007). Collectively, these findings demonstrated that multiple non-G mechanisms, either requiring or not requiring recruitment of  $\beta$ -arrestins and additional partners, can contribute to the activation of the ERK pathway by 5-HT receptors.

### Constitutive activity

Some GPCRs are capable of activating G proteins in the absence of agonists. This intrinsic activity was mainly established for heterogeneously expressed GPCRs, but also in authentic cellular contexts for some GPCRs. Some antagonists can inhibit these 'constitutive' activities and thus behave as 'inverse agonists'. Several 5-HT receptors exhibit constitutive activity in neurons. Constitutive activity at postsynaptic 5-HT<sub>1A</sub> receptors expressed in hippocampus has been described. Such an intrinsic activity has not been yet demonstrated for 5-HT<sub>1A</sub> autoreceptors (Martel *et al.*, 2007). As previously mentioned, constitutive activity of 5-HT<sub>2C</sub> receptors is highly dependent on the degree of mRNA edition: non-edited or partially

edited versions of the receptor exhibit the highest levels of constitutive activity, whereas the fully edited one is devoid of constitutive activity (Berg *et al.*, 2005; Chanrion *et al.*, 2008). Constitutive activation of non-edited or partially edited isoforms is associated with constitutive internalization (Marion *et al.*, 2004). Physiological constitutive activity of 5-HT<sub>2A</sub> receptors might explain impairment of associative learning by inverse agonists (Berg *et al.*, 2005). 5-HT<sub>4</sub> receptors display a particularly high constitutive activity in transfected cells, depending of the splice variant analyzed. The shorter ones exhibit a higher constitutive activity than the longer ones (Bockaert *et al.*, 2008). Unfortunately, no data are available concerning a possible *in vivo* existence of constitutive activity. Constitutive activity of native 5-HT<sub>7</sub> receptors also remains to be demonstrated (Millan *et al.*, 2008).

### Agonist-directed signaling

It has been recently proposed that a given GPCR can be stabilized under different active conformational states depending of the nature of the agonist – a phenomenon called 'ligand-directed signaling' (LDS) (Kenakin, 2007). LDS has been demonstrated for several 5-HT receptor subtypes. 5-HT<sub>1A</sub> receptor agonists show differential efficacies to stimulate various G proteins and to activate different channels such as GIRKs versus smooth inward-current channels ( $I_{\text{smooth}}$ ). The different efficacies of agonists at autoreceptors versus postsynaptic receptors might reflect their coupling to Gi<sub>3</sub> versus Go, respectively (Millan *et al.*, 2008). The rank order of efficacy for recruiting human 5-HT<sub>2C</sub> receptors differs for PLC versus PLA2 and for Gq/11 versus Gi<sub>3</sub>. Similarly, contrasting agonist efficacies at PLC versus PLA2 have been observed for human 5-HT<sub>2A</sub> receptors (Millan *et al.*, 2008). A particularly interesting example of LDS at 5-HT receptors is the different signaling induced by psychedelic hallucinogens (such as LSD, DOI and (–)DOB) versus non-hallucinogenic agonists (such as lisuride) of 5-HT<sub>2A</sub> receptors. Both ligand categories engage the Gq/PLC pathway, leading to *c-fos* induction in the somato-sensory cortex and the medial-prefrontal cortex (Figure 4) (Benneyworth *et al.*, 2007; Gonzalez-Maeso *et al.*, 2007). In contrast, only hallucinogenic drugs activate a Gi/o-Src pathway, leading to induction of *egr-2* expression in somato-sensory cortex and cortical neurons in primary culture (Gonzalez-Maeso *et al.*, 2007; Benneyworth *et al.*, 2007). Recent reports add to the complexity and interest of this hallucinogenic ligand and signaling. A physiological antagonism exists between 5-HT<sub>2A</sub> and mGlu<sub>2/3</sub> receptors in these cortical areas (Marek *et al.*, 2000). Activation of mGlu<sub>2/3</sub> receptors attenuates behavioral effects of hallucinogens known to

**Figure 4** Hallucinogens effects of some 5-HT<sub>2A</sub> agonists such as LSD and DOI: implication of ‘ligand directed signaling’ of 5-HT<sub>2A</sub> receptors and inhibition of hallucinogens effects by metabotropic glutamate receptors. (A) In somato-sensory cortex, Gonzalez-Maeso *et al.* (2008) showed a heterodimerization between mGluR<sub>2</sub> and 5-HT<sub>2A</sub> receptors. In cortical cultures and somato-sensory cortex, stimulation by non-hallucinogenic such as lisuride, 5-HT itself, and hallucinogenic drugs such as LSD and DOI engaged the Gq/G<sub>11</sub>/PLC/c-fos pathway (Gonzalez-Maeso *et al.*, 2007, 2008). (B) In cortical cultures (Gonzalez-Maeso *et al.*, 2007) and somato-sensory cortex (Gonzalez-Maeso *et al.*, 2007, 2008), hallucinogenic drugs such as LSD and DOI, but not non-hallucinogenic drugs, activated, in addition to the Gq/G<sub>11</sub>/PLC/c-fos pathway, the Gi/Go/Src/egr-2 pathway. In the somato-sensory cortex, activation of mGluR<sub>2</sub> with LY 341495 inhibited the Gi/Go/Src/egr-2 pathway but not the Gq/G<sub>11</sub>/PLC/c-fos pathway. LY 341495, an mGluR<sub>2</sub> orthosteric agonist, inhibited the stereotypical head-twitch behavior induced by hallucinogens (Gonzalez-Maeso *et al.*, 2008). (C) In the medial frontal cortex, the allosteric agonist BINA inhibited the stereotypical head-twitch behavior and c-fos induction of hallucinogens. Whether or not there is a regional difference (somato-sensory versus medial frontal cortex) between the control triggered by mGluR<sub>2</sub> on the c-fos induction by hallucinogens remains to be seen (Benneyworth *et al.*, 2007).

produce a state of drug intoxication that resembles many of the symptoms of acute schizophrenia (Marek *et al.*, 2000). Consistent with this hypothesis, data from a recent phase II clinical trial show that an mGlu<sub>2/3</sub> receptor agonist is an effective antipsychotic therapy (Aghajanian and Marek, 1999; Schoepp, 2006). The mechanism of mGlu<sub>2/3</sub> receptor agonist effect is controversial. mGlu<sub>2/3</sub> receptors are supposed to be localized on glutamatergic terminals connecting pyramidal neurons. 5-HT<sub>2A</sub> receptors are postsynaptically localized on layer V pyramidal neurons. Since activation of mGlu<sub>2/3</sub> receptors inhibits the 5-HT<sub>2A</sub> receptor-induced excitatory postsynaptic currents, the following hypothesis has been proposed to explain the effects of mGlu<sub>2/3</sub> receptors: (1) activation of postsynaptic layer V pyramidal neurons mediates induction of glutamate release from presynaptic nerve terminals connecting these neurons via a retrograde messenger; (2) glutamate induces postsynaptic excitatory currents in layer V pyramidal neurons, and it is this release which is inhibited following activation of presynaptic mGlu<sub>2/3</sub> receptors (Aghajanian and Marek, 1999; Benneyworth *et al.*, 2007). However, this hypothesis has been recently challenged by a report showing that mGlu<sub>2</sub> receptors can form heterodimers with 5-HT<sub>2A</sub> receptors in postsynaptic pyramidal neurons (Gonzalez-Maeso *et al.*, 2008). Activation of mGlu<sub>2</sub> receptors will ‘directly’ inhibit the hallucinogen-induced activation of the Gi/o–Src pathway, preventing induction of *egr-2* (Figure 4), without affecting the Gq–PLC pathway and *c-fos* induction (Gonzalez-Maeso *et al.*, 2008). This absence of inhibition of hallucinogen-induced Gq/c-fos pathway by mGlu<sub>2</sub> receptors observed in the somato-sensory cortex by Gonzalez-Maeso and colleagues contrasts with the observation made in the prefrontal cortex by Benneyworth and colleagues (2007). Further work is obviously needed to resolve this important paradox.

### Toward the notion of a 5-HT receptor complex

An increasing body of evidence indicates that 5-HT receptors are not ‘isolated islands’ floating within the plasma membrane, but that they are part of multiprotein complexes that incorporate a dimer (or an oligomer) of receptors associated with numerous intracellular proteins in addition to G proteins and the ubiquitous GPCR signaling modulators  $\beta$ -arrestins. To date, 5-HT receptors are among the GPCRs for which interacting proteins have been the most extensively characterized (Table 1), often by means of yeast two-hybrid screens or proteomic strategies. The list is still growing, and will continue to grow in the future, as the majority of interactions certainly remain to be discovered. Although the functional consequences of most of them remain to be established

**Table 1** Proteins identified as specific partners of 5-HT receptors and their role at the cellular level and *in vivo* (only receptor subtypes for which interacting proteins have been unambiguously identified are mentioned)

<sup>§</sup>Refers to experiments using receptors mutated on their PDZ binding motif.

<sup>§</sup>P11 binds to the third intracellular loop of 5-HT<sub>4</sub> receptors and therefore might equally interact with all receptor splice variants, including 5-HT<sub>4a</sub> and 5-HT<sub>4e</sub> receptors.

in authentic cellular contexts, a set of recent studies highlights their impact in CNS physiology and suggests their possible therapeutic exploitation for the treatment of CNS disorders. We do not provide an extensive description of 5-HT receptor interacting proteins here (see Table 1), as the majority of these interactions have been reviewed elsewhere (Bockaert *et al.*, 2004, 2006), but rather illustrate, using selected examples, their influence on receptor signal transduction and subcellular compartmentation and their possible implications in psychiatric disorders such as depression and addiction.

5-HT receptor-interacting proteins can modulate G protein-operated signaling by influencing localization of receptors at the plasma membrane, their desensitization and their coupling to G proteins. 5-HT<sub>2A/2C</sub> receptors express PDZ binding motifs at their C-terminal extremity, which recruit specific sets of PDZ domain-containing proteins (PDZ proteins) (Becamel *et al.*, 2002, 2004; Gavarini *et al.*, 2004). These interactions govern receptor trafficking in and out of the plasma membrane, and receptor desensitization. These effects depend on both the nature of the PDZ protein bound to the receptor and the receptor subtype. Association of the 5-HT<sub>2A</sub> receptor with PSD-95 stabilizes receptor at the plasma membrane (Xia *et al.*, 2003a). Accordingly, this interaction amplifies receptor-operated signals. In contrast, interaction of PSD-95 with 5-HT<sub>2C</sub> receptors increases spontaneous and agonist-dependent receptor internalization, whereas association of the receptor with another PDZ protein, MAGUK p55 subfamily member 3 (MPP3), prevents both receptor desensitization and internalization (Gavarini *et al.*, 2006). Overall, disruption of 5-HT<sub>2C</sub> receptor/PDZ protein interactions in cortical neurons increases

receptor desensitization, indicating that PDZ proteins predominantly inhibit receptor desensitization and internalization in neurons. Besides PDZ proteins, p11 (also called S100A10 or calpactin I light chain or annexin II light chain) is a member of the S100 Ca<sup>2+</sup>-binding protein superfamily that binds to several 5-HT receptor subtypes and affects receptor trafficking. Moreover, p11 is unique among the S100 family members for its capacity to interact with 5-HT receptors (Warner-Schmidt *et al.*, 2009). P11 was first identified, using yeast two-hybrid screening, as a 5-HT<sub>1B</sub> receptor interacting protein (Svenningsson *et al.*, 2006). P11/5-HT<sub>1B</sub> receptor interaction promotes receptor expression at the plasma membrane, and thereby enhances receptor signal transduction efficacy (Svenningsson *et al.*, 2006). More recently, a physical interaction between p11 and 5-HT<sub>4</sub> receptors has been described (Warner-Schmidt *et al.*, 2009). This interaction likewise increases 5-HT<sub>4</sub> receptor cell surface expression and downstream signaling.

Interaction of 5-HT receptors with accessory proteins also affects receptor phosphorylation and thereby receptor desensitization. 5-HT<sub>2A</sub> receptors (third intracellular loop) bind to p90 ribosomal S6 kinase 2 (RSK2), which induces receptor phosphorylation at Ser<sup>314</sup> located in the second intracellular loop (Sheffler *et al.*, 2006; Strachen *et al.*, 2008). Ser<sup>314</sup> phosphorylation leads to a tonic inhibition of receptor-operated signaling. Moreover, 5-HT<sub>2A</sub> receptor phosphorylation by RSK2 is required for epidermal growth factor-mediated heterologous desensitization of the 5-HT<sub>2A</sub> receptor. Another partner that might influence receptor phosphorylation and desensitization is calmodulin (CaM). The CaM binding site on the 5-HT<sub>2A</sub> receptor C-terminus overlaps with a putative PKC phosphorylation

site. In fact, CaM binding to the receptor C-terminus and receptor phosphorylation by PKC were found to be antagonistic, suggesting a role of CaM in the regulation of receptor desensitization (Turner and Raymond, 2005). CaM association with 5-HT<sub>1A</sub> receptor likewise interferes with receptor phosphorylation by PKC (Turner *et al.*, 2004).

Interacting proteins might also directly influence coupling of 5-HT receptors to G proteins. For instance, interaction of CaM with 5-HT<sub>2A</sub> receptors (second intracellular loop) prevents their coupling to Gq (Turner and Raymond, 2005), whereas receptor association with caveolins facilitates coupling to Gq (Bhatnagar *et al.*, 2004).

Beyond G protein-dependent signal transduction, interaction of 5-HT receptors with accessory proteins might promote non-G signaling. As already mentioned, constitutive interaction of 5-HT<sub>4</sub> receptor with Src is essential for receptor-operated ERK1,2 signaling, which is G-protein- and arrestin-independent (Barthet *et al.*, 2007). Activation of the ERK pathway by 5-HT<sub>2C</sub> receptor is likewise independent of the G proteins known to be activated by the receptor, but is intimately related to arrestin recruitment – a process facilitated by CaM bound to the receptor C-terminal domain (Labasque *et al.*, 2008). Thus, this non-G signaling seems to involve a tripartite ‘signalosome’ including the 5-HT<sub>2C</sub> receptor, CaM and  $\beta$ -arrestin. Finally, activation of the ERK pathway by the 5-HT<sub>6</sub> receptor, which is largely insensitive to PKA inhibition, is mediated by a direct interaction of Fyn (*via* its SH3 domain) with the receptor C-terminal domain (Yun *et al.*, 2007).

5-HT receptor-interacting proteins are not only important for signal transduction; they are also key determinants of subcellular distribution of 5-HT receptors. The 5-HT<sub>2A</sub> receptor PDZ binding motif is essential for the preferential receptor targeting to the dendritic compartment of pyramidal cortical neurons (Xia *et al.*, 2003b). The nature of the PDZ protein(s) that govern dendritic targeting of the receptor remains to be elucidated. PSD-95, the major receptor PDZ partner, is a possible candidate. In dendrites, the receptor is mainly confined in intracellular compartments. This intracellular localization seems to be related to its ability to interact with the microtubule-associated protein MAP1A (Cornea-Hebert *et al.*, 2002). Interaction of 5-HT<sub>1A</sub> receptor C-terminus with Yif1b, a protein of the endoplasmic reticulum/Golgi trafficking machinery, is essential for receptor targeting in the somatodendritic compartment (Carrel *et al.*, 2008).

The association of 5-HT<sub>2A</sub> receptor with caveolin-1, detected in both C6 glioma cells and rat brain synaptic membrane preparations, is essential for targeting the receptor to lipid rafts and, as mentioned above, for receptor-mediated signal transduction (Bhatnagar *et al.*, 2004). In pulmonary artery smooth muscle cells, the 5-HT<sub>2A</sub> receptor

forms a ternary complex with caveolin-1 and voltage-gated K<sup>+</sup> channels (K<sub>v</sub>1.5), which was found to be critical for 5-HT<sub>2A</sub> receptor-mediated inhibition of K<sub>v</sub>1.5 channels (Cogolludo *et al.*, 2006).

The essential role of 5-HT receptor-interacting proteins in modulating signal transduction suggests that these interactions might be physiologically relevant or contribute to pathological situations. Interaction of p11 with both 5-HT<sub>1B</sub> and 5-HT<sub>4</sub> receptors seems to be required for antidepressant actions of 5-HT<sub>1B</sub> and 5-HT<sub>4</sub> agonists (Svenningsson *et al.*, 2006; Warner-Schmidt *et al.*, 2009). Indeed, p11 knock-out mice exhibit a depression-like phenotype and reduced responsiveness to 5-HT<sub>1B</sub> and 5-HT<sub>4</sub> agonists in rodent behavioral models of depression. Further supporting a role of p11 in depression-like states, p11 brain expression is increased by antidepressant treatments, whereas the level of the protein is reduced in an animal model of depression as well as in the brain of patients who had suffered from unipolar major depression (Svenningsson *et al.*, 2006). Moreover, overexpression of p11 in neurons produces behavioral features reminiscent of those observed after antidepressant treatment. Collectively, these data suggest that alteration of 5-HT<sub>1B</sub> receptor/p11 and 5-HT<sub>4</sub> receptor/p11 interactions might contribute, at least in part, to the etiology of depressed states. 5-HT<sub>2C</sub> receptors interact with the tumor suppressor PTEN, an enzyme exhibiting both lipid and protein phosphatase activities (Ji *et al.*, 2006). This interaction was detected in dopaminergic neurons of the ventral tegmental area (VTA) innervating the accumbens nucleus, which are tonically inhibited by 5-HT<sub>2C</sub> receptors, and prevented agonist-induced receptor phosphorylation (Ji *et al.*, 2006). Disruption of 5-HT<sub>2C</sub> receptor/PTEN interaction in the VTA reproduced the inhibitory effect of 5-HT<sub>2C</sub> agonists on VTA dopaminergic neuron firing, and prevented the rewarding effects of cannabinoids that were mediated by increased activity of VTA dopaminergic neurons (Ji *et al.*, 2006). Importantly, disconnecting 5-HT<sub>2C</sub> receptors from PTEN did not reproduce the side effects evoked by 5-HT<sub>2C</sub> agonists, such as anxiety, penile erection, hypophagia, and suppression of locomotor activity. These data suggest that 5-HT<sub>2C</sub> receptor/PTEN interaction might contribute to the reinforcing role of drugs, and thereby constitutes a potential target for the treatment of drug addiction-related behaviors.

### 5-HT<sub>3</sub> receptor signaling

The signaling events associated with 5-HT<sub>3</sub> receptors are, in principle, very simple. Being cationic-channel permeable Na<sup>+</sup>, Ca<sup>2+</sup> and K<sup>+</sup>, activation of 5-HT<sub>3</sub> receptors

results in cell depolarization. 5-HT<sub>3</sub> receptors mediate fast synaptic responses postsynaptically, and stimulate the release of 5-HT and some other neurotransmitters presynaptically. There are discrepancies between the biophysical properties of the homo-pentameric 5-HT<sub>3A</sub> receptors and native 5-HT<sub>3</sub> receptors. Following the cloning of 5-HT<sub>3B</sub> receptors, these discrepancies have been, at least in part, solved by the observation that the 5-HT<sub>3AB</sub> receptors have properties more similar to native receptors. The complexity of native channels is likely to be much greater owing to the existence of splice variants of 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> receptors and the possible formation of hetero-pentamers between 5-HT<sub>3A</sub> and the newly cloned 5-HT<sub>3C-E</sub> forms (Jensen *et al.*, 2008).

**Abstract:** The almost incredible complexity of the 5-HT receptor family translates into the diversity of the brain distribution of these receptors, as briefly illustrated in this chapter. However, the picture is by no means complete, due either to the lack of tools for some of these receptors or their components (selective ligands or good antibodies that label exclusively a single receptor are still rare) and/or to the genomic complexity of some of these receptors; thus 5-HT<sub>4</sub> and 5-HT<sub>7</sub> receptors come in numerous splice variants, the 5-HT<sub>2C</sub> receptor has even more potential editing variants, whereas the 5-HT<sub>3</sub> receptor has multiple potential subunits. There is debate as to which of the latter are co-expressed and form functional receptors, or which splice/editing variants of the former are expressed and where. In addition, one tends to be misled by density – for example, the 5-HT<sub>2C</sub> receptor is not only a choroid plexus receptor, the dorsal raphe nucleus expresses more than just 5-HT<sub>1A</sub> receptors, and it may be premature to suggest that the low density of 5-HT<sub>3</sub> receptors outside of the brainstem has low functional relevance. The 5-HT<sub>1e</sub> receptor is not expressed in rodents, and 5-HT<sub>5b</sub> receptors do not exist in man; in addition, both receptors share an almost total lack of adequate tools for their identification. On the other hand, we have tried to illustrate the fact that initial receptor distribution studies have been crucial in the definition of new 5-HT receptors, especially in the days preceding molecular biology/receptor cloning, and that the knowledge of receptor distribution in health and disease is essential for a (patho)physiological understanding of their function.

**Keywords:** 5-HT receptor families and subtypes, autoradiography, *in situ* hybridization, immunocytochemistry, brain distribution, species differences.

## Introduction

The serotonin (5-HT, 5-hydroxytryptamine) system is one of the oldest neurotransmitter/hormone systems in evolution, probably as old as 800 million years; this may explain why 5-HT interacts with such a diversity of receptors of the G-protein-coupled family (GPCRs) and the ligand-gated ion channel family. This is similar to other ‘old’ neurotransmitters, such as acetylcholine, GABA or glutamate, which also have high levels of complexity, although the latter neurotransmitters show a high diversity at the level of their ligand-gated channel receptors, whereas 5-HT’s complexity lies primarily at the levels of its many GPCRs. 5-HT was discovered in the gut in the 1930s and called enteramine, then rediscovered in the 1940s in the blood and called serotonin, based on its vasoconstrictor features.

Although the major production of 5-HT is in the periphery, the brain has its share of 5-HT and related receptors and transporters, which in a number of cases appear to be involved in neurological or neuropsychiatric pathologies, such as mood disorders, anxiety and depression, schizophrenia and psychosis, addiction, memory impairment, pain, migraine, and chemotherapy- or surgical-induced vomiting where the trigger zones are central. It is therefore not surprising that 5-HT, tryptophan hydroxylases, the 5-HT transporter and a great variety of 5-HT receptors are to be found in the brain, some receptors having highly localized patterns, whereas others may be rather widespread. We will keep to the nomenclature that has been adopted and refined by the serotonin nomenclature committee (Hartig *et al.*, 1993; Hoyer *et al.*, 1994, 2002).

## 5-HT<sub>1A</sub> receptors

The 5-HT<sub>1A</sub> receptor was the first of the 5-HT family to be cloned (Kobilka *et al.*, 1987; Fargin *et al.*, 1988); it

\*Corresponding author  
E-mail: daniel.hoyer@novartis.com

was also the first for which really selective ligands were described, such as 8-OH-DPAT (Gozlan *et al.*, 1983; Middlemiss and Fozard, 1983). This had a tremendous impact on the pharmacological characterization of 5-HT receptors in general and that of 5-HT<sub>1A</sub> in particular, including the distribution of 5-HT<sub>1A</sub> receptors in the brain, since [<sup>3</sup>H]-8-OH-DPAT was an excellent ligand for membrane binding (Gozlan *et al.*, 1988, 1995; Hoyer *et al.*, 1985a), but also in the performance of autoradiography in tissue slices of various species (Pazos and Palacios, 1985; Pazos *et al.*, 1987a). 8-OH-DPAT also allowed the definition of non-5-HT<sub>1A</sub> sites, which developed rather rapidly in the mid-1980s (Hoyer *et al.*, 1986a; Bruinvels *et al.*, 1992; Waeber and Palacios, 1992), in both radioligand binding and autoradiographic studies. These allowed comparison of brain distribution patterns in various species, which meant that receptors could be distinguished or regrouped even when the pharmacological signature was different across species (Hoyer and Middlemiss, 1989). Although we now know that 8-OH-DPAT has some affinity for 5-HT<sub>7</sub> receptors (Tsou *et al.*, 1994), the conditions under which autoradiography was performed excluded significant binding to 5-HT<sub>7</sub> sites.

Thus, the brain distribution of 5-HT<sub>1A</sub> receptors has been studied extensively by receptor autoradiography using a range of agonists, including initially [<sup>3</sup>H]-5-HT, [<sup>3</sup>H]-8-OH-DPAT, [<sup>3</sup>H]-ipsapirone, [<sup>125</sup>I]-BH-8-MeO-N-PAT (Pazos and Palacios, 1985; Palacios *et al.*, 1987; Ponchant *et al.*, 1988) and more recently a few antagonists [<sup>125</sup>I]-p-MPPI and [<sup>3</sup>H]-WAY 100635 (Laporte *et al.*, 1994) which allow *in vivo* labeling of 5-HT<sub>1A</sub> receptors. PET studies have used [<sup>11</sup>C]-WAY 100635 and related compounds (Sandell *et al.*, 2001) to image 5-HT<sub>1A</sub> receptors in the living human brain.

The density of 5-HT<sub>1A</sub> binding sites is high in limbic brain areas, notably hippocampus (Figure 1B), lateral septum, cortical areas (particularly cingulate and entorhinal cortex), and the mesencephalic raphe nuclei (both dorsal and median raphe nuclei) (Figure 1D). In contrast, levels of 5-HT<sub>1A</sub> binding sites in the basal ganglia and cerebellum are barely detectable. 5-HT<sub>1A</sub> receptors are located both postsynaptic to 5-HT neurons (in forebrain regions) and also on the 5-HT neurons themselves at the level of the soma and dendrites in the mesencephalic and medullary raphe nuclei. This is evident from studies on the effects of neuronal lesions on 5-HT<sub>1A</sub> binding sites and mRNA, and studies of the cellular localization of the 5-HT<sub>1A</sub> receptor using immunocytochemistry (Kia *et al.*, 1996a). The distribution of mRNA encoding the 5-HT<sub>1A</sub> receptor is almost identical to that of the 5-HT<sub>1A</sub> binding site (Figure 1A–D) (Pompeiano *et al.*, 1992). Antibodies have been generated to study 5-HT<sub>1A</sub> receptor distribution in the brain. In general, there is good agreement

between the distribution of 5-HT<sub>1A</sub> binding sites and signals obtained using immunocytochemistry. At the cellular level, *in situ* hybridization and immunocytochemical studies demonstrate the presence of 5-HT<sub>1A</sub> receptors in cortical pyramidal neurons as well as pyramidal and granular neurons of the hippocampus (Figure 1A). The 5-HT<sub>1A</sub> receptor is expressed in 5-HT-containing neurons in the raphe nuclei (Figure 1C), cholinergic neurons in the septum, and (probably) glutamatergic (pyramidal) neurons in the cortex and hippocampus (DeFelipe *et al.*, 2001; Santana *et al.*, 2004; de Almeida and Mengod, 2008). They are co-expressed with the 5-HT<sub>2A</sub> receptors in the pyramidal cells of the rat prefrontal cortex (Amargós-Bosch *et al.*, 2004). The ultrastructural location of the 5-HT<sub>1A</sub> receptor identifies synaptic membranes, as well as extrasynaptic structures (Kia *et al.*, 1996b). There are reports of 5-HT<sub>1A</sub> receptors in brain glial cells, but this has not been confirmed. In the human brain, similar findings have been reported whether the older or more recent tools have been used (Pazos *et al.*, 1987a; Varnas *et al.*, 2004a). The pattern of 5-HT<sub>1A</sub> receptor distribution is similar across species, although the laminar organization of the 5-HT<sub>1A</sub> receptor in cortical and hippocampal areas of humans differs somewhat from that in the rodent (Santana *et al.*, 2004; de Almeida and Mengod, 2008).

### 5-HT<sub>1B</sub> receptors

The 5-HT<sub>1B</sub> receptor was initially rather loosely defined as non-5-HT<sub>1A</sub>; in other words, [<sup>3</sup>H]-5-HT sites which were not sensitive to 8-OH-DPAT (Middlemiss and Fozard, 1983; Pazos and Palacios, 1985), had high affinity for some beta-blocking ligands such as [<sup>125</sup>I]-cyanopindolol in rodents (Hoyer *et al.*, 1985b), but much less so in non-rodents and primates (Hoyer *et al.*, 1986a). This is when the difficulty started, as the rodent receptor was then defined as 5-HT<sub>1B</sub> (also in opossum) and the non-rodent receptor (pig, calf, monkey, human and other species) as 5-HT<sub>1D</sub>, since no pharmacologically equivalent site could be described in non-rodent species (Hoyer *et al.*, 1986a). However, based on similarities in coupling, function and distribution (for example, inhibition of adenylate cyclase activity, autoreceptor activity, and marked expression in striatum/substantia nigra), we proposed these two apparently pharmacologically distinct receptors (5-HT<sub>1B</sub> and 5-HT<sub>1D</sub>) would be species homologs (Hoyer and Middlemiss, 1989). This was then confirmed with the cloning of all members of the 5-HT<sub>1</sub> receptor family and with the availability of much more selective tools – for example, 5-HT<sub>1B</sub>-selective and 5-HT<sub>1D</sub>-selective ligands such as SB 224289 and BRL15572, respectively. The situation is still somewhat confused, since the 5-HT<sub>1D</sub> and

**Figure 1** Autoradiographic distribution of radioligand binding sites and mRNA for several 5-HT receptor subtypes in the rat brain. Images are photomicrographs from film autoradiograms where dark areas correspond to regions rich in binding sites or mRNA. (A, C) Distribution of mRNA coding for 5-HT<sub>1A</sub> receptors detected with <sup>33</sup>P-labeled oligonucleotide probes at two coronal levels of the rat brain. (B, D) Distribution of 5-HT<sub>1A</sub> receptors labeled by [<sup>3</sup>H]8-OH-DPAT (1 nM) in close sections. (E, F) Distribution of 5-HT<sub>1B/1D</sub> receptors labeled by [<sup>3</sup>H]GR 125743 (1 nM). (G, H) Distribution of binding sites labeled by [<sup>3</sup>H]-Sumatriptan (5 nM) alone, which labels 5-HT<sub>1B</sub>, 5-HT<sub>1D</sub>, and 5-HT<sub>1F</sub> receptors (G), or in the presence of 10-nM 5-CT (5-carboxamidotryptamine), which results in the preferential visualization of 5-HT<sub>1F</sub> receptors (H). (I) Distribution of 5-HT<sub>2A</sub> receptors labeled by [<sup>3</sup>H]MDL 100,907 (0.4 nM). (J, K) Distribution of sites labeled by [<sup>3</sup>H]Mesulergine (5 nM) in coronal (J) and sagittal (K) sections. Note the very high densities of labeled sites in the choroid plexus that correspond to 5-HT<sub>2C</sub> receptors. The autoradiographic signal in cortical regions represents mainly binding of the radioligand to 5-HT<sub>2A</sub> receptors. (L, N) Distribution of mRNA coding for 5-HT<sub>4</sub> receptors detected with <sup>33</sup>P-labeled oligonucleotide probes that recognize all known splice variants of this receptor subtype. (M, O) Distribution of 5-HT<sub>4</sub> receptors labeled by [<sup>125</sup>I]SB 207710 (0.02 nM) in close sections. Scale bars: 3 mm. The bar in O applies to all the coronal sections (Cg, cingulate cortex; ChP, choroid plexus; CPu, caudate putamen; DG, dentate gyrus; DR, dorsal raphe nucleus; Ent, entorhinal cortex; FR, fasciculus retroflexus; GP, globus pallidus; Hip, hippocampus; IC, inferior colliculus; M, motor cortex; PF, parafascicular thalamic nucleus; PrL, prelimbic cortex; S, subiculum; SN, substantia nigra; SuG, superficial gray layer of the superior colliculus; ZI, zona incerta).

5-HT<sub>1B</sub> receptors remain very similar, in pharmacological terms especially, in non-rodents, and coexist in most species. They even seem to be similarly distributed, but it is very difficult to demonstrate the presence of significant amounts of 5-HT<sub>1D</sub> protein or mRNA in the brain, whereas 5-HT<sub>1B</sub> is strongly expressed across species. From this discussion, it is evident that brain receptor distribution studies have been an integral part of the process of 5-HT receptor discovery and characterization.

Autoradiographic studies using [<sup>3</sup>H]-5-HT (in the presence of 8-OH-DPAT) (Pazos and Palacios, 1985), [<sup>125</sup>I]-cyanopindolol (in the presence of isoprenaline) (Hoyer *et al.*, 1985b) or [<sup>125</sup>I]-GTI (serotonin-5-O-carboxymethyl-glycyl-[<sup>125</sup>I]tyrosinamide) (Waeber *et al.*,

1990) demonstrate a high density of 5-HT<sub>1B</sub> sites in the rat basal ganglia, particularly the substantia nigra, globus pallidus, ventral pallidum and entopeduncular nucleus, but also many other regions. With appropriate displacing agents, both [<sup>125</sup>I]-cyanopindolol and [<sup>125</sup>I]-GTI allow discrimination of 5-HT<sub>1B</sub> binding sites from 5-HT<sub>1D</sub> binding sites in rodents, but currently there are no selective radioligands that allow this in non-rodent species (Waeber *et al.*, 1988a). The discrimination of 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors in both rodent and non-rodent species has become more straightforward with the availability of a new 5-HT<sub>1B/1D</sub> radioligand, [<sup>3</sup>H]-GR125743 (Figure 1E, F), as well as cold ligands which discriminate 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors. However, [<sup>3</sup>H]-GR125743,

[<sup>3</sup>H]-L-694,247 and [<sup>3</sup>H]-Sumatriptan share these features, the latter also being able to label 5-HT<sub>1F</sub> receptors (Figure 1G, H). Evidence from radioligand binding experiments using 5-HT neuronal lesions is equivocal regarding the synaptic location of the rat 5-HT<sub>1B</sub> receptor, with some studies finding that the lesion causes upregulation of 5-HT<sub>1B</sub> binding sites and others finding downregulation in the same areas. However, *in situ* hybridization studies have located mRNA encoding the 5-HT<sub>1B</sub> receptor in the dorsal and median raphe nuclei. Furthermore, 5-HT<sub>1B</sub> receptor mRNA in the raphe nuclei is markedly reduced by a 5-HT neuronal lesion. Together, these data suggest that 5-HT<sub>1B</sub> receptors are located both presynaptically and postsynaptically relative to 5-HT neurons. It is speculated that in some brain areas (including substantia nigra and globus pallidus) 5-HT<sub>1B</sub> binding sites may be located on non-5-HT nerve terminals, having been synthesized and then transported from cell bodies in other regions. Overall, the anatomical location of the 5-HT<sub>1B</sub> receptor provides strong evidence to support the idea that the 5-HT<sub>1B</sub> receptor has a role as both a 5-HT autoreceptor and a 5-HT heteroreceptor – i.e., controlling transmitter release. The receptors are also found on cerebral arteries and other vascular tissues, but no binding studies have confirmed this. Further, it seems that the receptor is ‘silent’ and may become responsive in conditions such as atherosclerosis, or at least needs some trigger. Peripheral effects have been described, such as inhibition of noradrenaline release in the vena cava and inhibition of plasma extravasation produced by trigeminal ganglion stimulation in guinea pigs and rats. 5-HT<sub>1B</sub> receptors mediate contraction of rat caudal arteries. In non-rodents, they exhibit the 5-HT<sub>1D</sub> ‘pharmacology’.

Some forebrain areas with high levels of 5-HT<sub>1B</sub> binding sites (e.g., striatum) also express 5-HT<sub>1B</sub> receptor mRNA. However, other areas with high levels of 5-HT<sub>1B</sub> binding sites have little detectable mRNA (e.g., substantia nigra, globus pallidus and entopeduncular nucleus). Similar mismatches between brain distribution of 5-HT<sub>1B</sub> receptor mRNA and binding sites have been found in the primate and human brain (Varnas *et al.*, 2004a, 2004b). At the cellular level, *in situ* hybridization studies have localized 5-HT<sub>1B</sub> receptor mRNA to granule and pyramidal cells within the hippocampus, and medium spiny neurons of the caudate putamen which are probably GABAergic. Immunocytochemical studies are now necessary to reveal the synaptic location of the receptors. mRNA has been located to some blood vessels. Antibodies are available, and have been used to label 5-HT<sub>1B</sub> receptors in the brain of rodents.

Very recently, [<sup>3</sup>H]AZ10419369 and its [<sup>11</sup>C] analog have been described in autoradiographic studies in both macaque and human brain. Altogether, the data suggest

that [<sup>11</sup>C]AZ10419369 is a suitable radioligand for PET studies on 5-HT<sub>1B</sub> receptor distribution and occupancy *in vivo* (Pierson *et al.*, 2008).

## 5-HT<sub>1D</sub> receptors

5-HT<sub>1D</sub> receptor has been cloned, and functionally expressed in recombinant systems; ligands can label it specifically (Zgombick *et al.*, 1995, 1996, 1997), although most of them will also label 5-HT<sub>1B</sub> receptors (see above). 5-HT<sub>1D</sub> selective antagonists have been developed for migraine, with the hope of avoiding cardiovascular side effects, but with less success than anticipated (see, for example, PNU-142633; McCall *et al.*, 2002), especially since both 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors are present in the trigeminal ganglion (Hou *et al.*, 2001). It may well be that the 5-HT<sub>1B</sub> component in the triptans is essential for their therapeutic effects. However, to determine the true contribution of 5-HT<sub>1D</sub> in brain binding has proven difficult because of very low 5-HT<sub>1D</sub> expression levels and the fact that, when present, 5-HT<sub>1D</sub> mRNA is expressed in regions where much higher levels of 5-HT<sub>1B</sub> mRNA have been found, and presumably the same is true for the corresponding proteins (Bruinvels *et al.*, 1993, 1994).

*In situ* hybridization allows detection of 5-HT<sub>1D</sub> mRNA in rat brain regions, including the caudate putamen, nucleus accumbens, olfactory cortex, dorsal raphe nucleus and locus coeruleus. mRNA had low abundance in all regions but, interestingly, was undetectable in certain regions, including the globus pallidus, ventral pallidum and substantia nigra, where 5-HT<sub>1B/1D</sub> binding sites appear to be present. Together, these data are reminiscent of the findings with the 5-HT<sub>1B</sub> receptor, and indicative of the 5-HT<sub>1D</sub> receptor being located predominantly on axon terminals of both 5-HT and non-5-HT neurons.

It has been difficult to determine the distribution of 5-HT<sub>1D</sub> receptors (see above) because protein levels appear to be low and there is a lack of radioligands able to discriminate 5-HT<sub>1D</sub> from 5-HT<sub>1B</sub> receptors (Schlicker *et al.*, 1997a, 1997b). Autoradiographic studies in rat utilizing [<sup>125</sup>I]-GTI (serotonin-5-O-carboxymethyl-glycyl-[<sup>125</sup>I]tyrosinamide) in the presence of CP 93129 to mask the rat 5-HT<sub>1B</sub> binding site suggest that the 5-HT<sub>1D</sub> site is present in various regions, but especially the basal ganglia (particularly the globus pallidus, substantia nigra and caudate putamen) and also the hippocampus and cortex. The distribution of 5-HT<sub>1D</sub> receptors in human brain, as defined by the ketanserin-sensitive component of the [<sup>3</sup>H]-Sumatriptan binding site, indicated their presence in the basal ganglia (globus pallidus and substantia nigra) as well as specific regions of the midbrain (periaqueductal gray) and spinal cord (Varnas *et al.*, 2001).

## 5-HT<sub>1E</sub> receptors

The 5-HT<sub>1E</sub> receptor was first detected in human brain membranes (this is crucial, see below) using radioligand binding studies that found that [<sup>3</sup>H]5-HT, in the presence of blocking agents for other 5-HT<sub>1</sub> subtypes that were known at that time (5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>1C/2C</sub>), demonstrated a biphasic competition curve to 5-HT (Leonhardt *et al.*, 1989; Miller and Teitler, 1992; Bruinvels *et al.*, 1993; Barone *et al.*, 1994). The site with high affinity for 5-HT was thought to represent the 5-HT<sub>1D</sub> receptor. The low-affinity site had an unknown pharmacology, and was suggested to be a novel 5-HT receptor (5-HT<sub>1E</sub>). Although 5-HT<sub>1E</sub> binding sites have been described in rodents, the relevance of these sites remains enigmatic as the receptor has not been cloned from rats or mice (Hoyer *et al.*, 1994), presumably because the gene is non-functional. Thus, the so-called rodent 5-HT<sub>1E</sub> sites that have been reported cannot be 5-HT<sub>1E</sub> receptors.

The 5-HT-insensitive [<sup>3</sup>H]5-HT binding site was found in the cortex and caudate membranes of human, but also in guinea pig, rabbit and dog. Although we now know that other 5-HT receptor subtypes also have high affinity for [<sup>3</sup>H]5-HT, are 5-HT insensitive (5-HT<sub>1F</sub>, 5-HT<sub>6</sub>) and have probably contributed to the initially described 5-HT<sub>1E</sub> binding, a human gene encoding for a receptor with 5-HT<sub>1E</sub> pharmacology (and structural features typical of a 5-HT<sub>1</sub> receptor) was subsequently isolated (McAllister *et al.*, 1992; Adham *et al.*, 1994a). In spite of the absence of selective radioligands for the 5-HT<sub>1E</sub> receptor, autoradiographic studies have provided a picture of the distribution of non-5-HT<sub>1A/1B/1D/2C</sub> [<sup>3</sup>H]5-HT binding sites in human, rat, mouse and guinea-pig brain using rather complex technical conditions with co-incubation of ligands to block binding to the other known 5-HT<sub>1</sub> receptors. These studies indicate that, in all species, higher levels of these binding sites are present in the cortex (particularly entorhinal cortex), caudate putamen and claustrum, with detectable levels in other areas, such as the hippocampus (subiculum) and amygdala.

In hindsight, these receptor autoradiography studies may have been detecting a combination of 5-HT<sub>1E</sub> and 5-HT<sub>1F</sub> binding sites, and they were rather predictive. Thus, in the human and monkey brain, 5-HT<sub>1E</sub> mRNA is present in cortical areas (including entorhinal cortex) and the caudate and putamen, with lower levels in the amygdala and hypothalamus (Bruinvels *et al.*, 1994; Mengod *et al.*, 2006). 5-HT<sub>1E</sub> mRNA appears to be postsynaptic, consistent with receptor autoradiography studies finding no change in levels of the 5-HT<sub>1E</sub> binding site in rat forebrain following 5-HT neuronal lesions, but these studies were performed in rats.

The human (Lovenberg *et al.*, 1993) and the guinea-pig receptors have been cloned (Bai *et al.*, 2004), but remain

enigmatic in both function and distribution; related to this, there are no selective ligands that allow a clear-cut functional or anatomical characterization of that receptor. Since the receptor is not expressed in the most commonly used laboratory animals, rat and mouse, the usual approach to create knock-out (KO) animals to study a phenotype that may be linked to lack of receptor expression or even the receptor KO/beta galactosidase knock-in is not very helpful for the study of either the distribution or the function. In addition, the guinea pig is not a favored species in behavioral studies, especially when selective tools are absent.

## 5-HT<sub>1F</sub> receptors

The 5-HT<sub>1F</sub> receptor could be described as a pure product of molecular biology: it was identified by homology screening starting from the existing known 5-HT<sub>1</sub> receptor sequences (Adham *et al.*, 1996, 1997). The receptor is still relatively poorly characterized; it is pharmacologically and structurally close to 5-HT<sub>1E</sub>, but has been the subject of intense research (Adham *et al.*, 1994b; Phebus *et al.*, 1996) since Sumatriptan, the 5-HT<sub>1B/1D</sub> agonist, also has affinity for 5-HT<sub>1F</sub> receptors. Thus it was hypothesized that 5-HT<sub>1F</sub> receptor modulation may be a new approach in migraine intervention without the cardiovascular side effects of the triptans, since there is no evidence for functional vascular 5-HT<sub>1F</sub> receptors (Johnson *et al.*, 1997; Mitsikostas *et al.*, 1999).

Initial studies located 5-HT<sub>1F</sub> mRNA in the mouse and guinea-pig brain using *in situ* hybridization. 5-HT<sub>1F</sub> mRNA was found in hippocampus (CA1–CA3 cell layers), cortex (particularly cingulate and entorhinal cortices), and dorsal raphe nucleus (Bruinvels *et al.*, 1994). These results were confirmed in a subsequent more detailed mapping in the guinea-pig brain (Adham *et al.*, 1997), although levels of 5-HT<sub>1F</sub> mRNA in the raphe nuclei appeared to be much less abundant than in the initial report.

Brain regions containing 5-HT<sub>1F</sub> mRNA also display 5-HT-insensitive 5-HT<sub>1</sub>, but non-5-HT<sub>1A/1B/2C/1D</sub> sites as detected in autoradiography studies. In autoradiography studies, [<sup>3</sup>H]-Sumatriptan was used in the presence of 5-HT to label 5-HT<sub>1F</sub> binding sites in the guinea pig, rat (Figure 1G, H) and human brain (Lovenberg *et al.*, 1993; Waeber and Moskowitz, 1995; Mengod *et al.*, 1996; Palacios *et al.*, 1996). The distribution of 5-HT-insensitive [<sup>3</sup>H]-Sumatriptan binding sites demonstrates a very good correlation with that of 5-HT<sub>1F</sub> mRNA (in the guinea pig) with the highest levels of binding in cortical and hippocampal areas, the claustrum and the caudate nucleus. Although the receptor is located in various parts of the

basal ganglia, in contrast to 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> binding sites, 5-HT<sub>1F</sub> binding sites appear to be barely detectable in the substantia nigra.

The brain distribution of 5-HT<sub>1F</sub> sites became more precise (or more convincing) as labeled by the selective 5-HT<sub>1F</sub> radioligand, [<sup>3</sup>H]LY334370 (Lucaites *et al.*, 2005). In rat brain, specific 5-HT<sub>1F</sub> binding was found in layers IV–V of cortical regions, the olfactory bulb and tubercle, nucleus accumbens, caudate putamen, parafascicular nucleus of the thalamus, medial mammillary nucleus, CA3 region of the hippocampus, subiculum, and amygdaloid nuclei. Interestingly, rat-brain autoradiography with [<sup>3</sup>H]LY334370 and [<sup>3</sup>H]-Sumatriptan showed labeling in the same brain regions when performed side by side. Some species differences in the distribution of the 5-HT<sub>1F</sub> receptor were noted between rat, guinea pig, monkey and human brain. 5-HT<sub>1F</sub> receptors have not been found in blood vessels, which is interesting in the context of migraine.

### 5-HT<sub>2A</sub> receptors

The 5-HT<sub>2A</sub> receptor is the classical 5-HT<sub>2</sub> or 5-HT<sub>D</sub> receptor which was originally identified in the vascular (most blood vessels) and non-vascular smooth muscle (e.g., guinea-pig ileum). The receptor is also present in platelets and is rather prominently expressed in the brain. We were in the fortunate situation very early on to have adequate radioligands with good selectivity to label 5-HT<sub>2A</sub> receptors – for example, [<sup>3</sup>H] ketanserin or [<sup>3</sup>H] spiperone (under appropriate conditions, since ketanserin can label α<sub>1</sub> adrenoceptors and spiperone has also high affinity for D<sub>2</sub> receptors) (Hoyer *et al.*, 1987). These ligands allowed good definition of the distribution of 5-HT<sub>2A</sub> receptors even before it became apparent that subtypes of 5-HT<sub>2</sub> receptors existed (5-HT<sub>2B</sub> and 5-HT<sub>2C</sub>) (Hoyer *et al.*, 1986b). Such information regarding the receptor distribution was crucial, when the list of 5-HT<sub>2</sub> receptors expanded. Thus, it was found that [<sup>3</sup>H]5-HT labeled sites in the choroid plexus were not identified by [<sup>3</sup>H]ketanserin but by [<sup>3</sup>H]mesulergine, a ligand known to bind dopamine D<sub>2</sub> and 5-HT<sub>2</sub> receptors (Pazos *et al.*, 1984a). An extensive pharmacological and distribution characterization (Pazos *et al.*, 1984b) led to the conclusion that the new sites could not be the classical 5-HT<sub>2</sub> receptors, and we proposed naming it 5-HT<sub>1C</sub> (because of its high affinity for 5-HT), to be renamed later 5-HT<sub>2C</sub> due to clear structural and transductional homology with the 5-HT<sub>2</sub> class.

More recently, [<sup>3</sup>H]MDL 100,907 (also known as M 100,907) (Figure 11) became another very selective tool to study 5-HT<sub>2A</sub> receptors *in vitro*, and [<sup>11</sup>C] analogs can be

used *in vivo* for PET studies (Ito *et al.*, 1998). LSD and its derivatives do label 5-HT<sub>2</sub> receptors, but are not selective, similar to the agonist DOI. High levels of 5-HT<sub>2A</sub>-binding sites have been found in cortical areas, the caudate, nucleus accumbens, olfactory tubercle and hippocampus (Pazos *et al.*, 1985, 1987b; López-Giménez *et al.*, 1997, 2001a). Generally, there is close overlap between the distribution of 5-HT<sub>2A</sub>-binding sites, immunoreactivity and mRNA, suggesting that this subtype has a postsynaptic location (López-Giménez *et al.*, 1997, 1998, 1999, 2001a, 2001b). In areas such as the cortex, 5-HT<sub>2A</sub> receptors have been localized on GABAergic interneurons and also on glutamatergic projection neurons (Santana *et al.*, 2004; de Almeida and Mengod, 2007). The distribution of human 5-HT<sub>2A</sub> receptors has been successfully mapped using various tools, and altogether the data were consistent with rodent data (Pazos *et al.*, 1987b; Varnas *et al.*, 2004a). A peculiarity of the human 5-HT<sub>2A</sub> receptor is its location in striosomes (Waeber and Palacios, 1994; López-Giménez *et al.*, 1999).

### 5-HT<sub>2B</sub> receptors

The receptor was first identified in the rat fundus, but is also present in a number of vessels and the heart (Ullmer *et al.*, 1995). The receptor has been cloned (Foguet *et al.*, 1992; Schmuck *et al.*, 1994; Wainscott *et al.*, 1996), and received a great deal of attention more recently when it was established that fenfluramine caused valvulopathies by indirect activation of the 5-HT<sub>2B</sub> receptor (Fitzgerald *et al.*, 2000). Initially its presence in the brain was largely neglected, since *in situ* hybridization studies did not provide positive data. However, the presence of 5-HT<sub>2B</sub> receptor-like immunoreactivity was eventually reported in rat brain, although the immunostaining is restricted to a few regions, particularly the cerebellum, lateral septum, dorsal hypothalamus and medial amygdala (Duxon *et al.*, 1997). The cells expressing 5-HT<sub>2B</sub> receptor-like immunoreactivity have a neuronal rather than astrocytic morphology. The brain 5-HT<sub>2B</sub> receptor's function remains to be described.

### 5-HT<sub>2C</sub> receptors

The 5-HT<sub>2C</sub> was discovered by the combined use of membrane receptor binding/pharmacology and brain-slice autoradiography, where an atypical 5-HT binding site was identified initially. We had noticed the presence of a 5-HT site in the choroid plexus which was not 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> or 5-HT<sub>2A</sub>, and was then named 5-HT<sub>1C</sub>. The pharmacology and distribution of the new site was

different from what was known (Hoyer *et al.*, 1985a; Pazos *et al.*, 1984a, 1984b), and this putative 5-HT receptor was found across species in the choroid plexus and other brain regions. Radioligands that label 5-HT<sub>2C</sub> receptors are [<sup>3</sup>H]mesulergine (in the presence of a selective 5-HT<sub>2A</sub> antagonist), [<sup>3</sup>H]5-HT (with adequate protection using a cocktail of 5-HT<sub>1</sub> ligands), [<sup>125</sup>I]SCH23982 (also dopamine D1), [<sup>125</sup>I]LSD (in the presence of adequate 5-HT<sub>2A</sub> selective drugs) and the 5-HT<sub>2</sub> receptor agonist [<sup>125</sup>I]DOI (also in the presence of selective 5-HT<sub>2A</sub>-blocking drug).

5-HT<sub>2C</sub> receptor localization is restricted to the CNS, unlike that of 5-HT<sub>2A</sub> and 5-HT<sub>2B</sub> receptors. Autoradiographic studies have identified this receptor in the choroid plexus, cortex, nucleus accumbens, hippocampus, amygdala, caudate and substantia nigra in rat brain. The 5-HT<sub>2C</sub> receptors, in addition to having a postsynaptic location, may also be presynaptic. In the mouse, [<sup>3</sup>H]mesulergine binding sites (in the presence of spiperone to block binding to 5-HT<sub>2A</sub> receptors; Mengod *et al.*, 1990) throughout the wild-type brain show strong labeling in choroid plexus, which is predominant, although the presence of low/very low specific [<sup>3</sup>H]mesulergine signals are detected in the nucleus accumbens, patches of the caudate putamen, the olfactory tubercle, claustrum, septum, cingulate cortex, amygdala, dentate gyrus, periaqueductal gray, entorhinal cortex, and several brainstem motor nuclei. This binding is no longer detected in the 5-HT<sub>2C</sub> receptor knock-out mouse brain (López-Giménez *et al.*, 2002), making the point that 5-HT<sub>2C</sub> receptors are indeed present in the brain, although at much lower densities than 5-HT<sub>2A</sub> receptors (with the remarkable exception of the choroid plexus). The distribution of mRNA is very similar to that of protein or binding sites, except for high levels in the habenular nucleus, where binding site levels are very low (Mengod *et al.*, 1990; López-Giménez *et al.*, 2001c). There are multiple splice and editing variants of 5-HT<sub>2C</sub> receptors (Niswender *et al.*, 1998; Fitzgerald *et al.*, 1999) which are beyond the scope of this chapter; they are not discriminated as far as is known by the antagonist radioligands used in autoradiographic studies.

In monkey, 5-HT<sub>2C</sub> mRNA is present in the choroid plexus, in layer V of most cortical regions, in the nucleus accumbens, ventral anterior caudate and putamen, septal nuclei, diagonal band, ventral striatum and extended amygdala (López-Giménez *et al.*, 2001c). Several thalamic, midbrain and brainstem nuclei also express 5-HT<sub>2C</sub> mRNA. [<sup>3</sup>H]mesulergine binding and mRNA showed a good correlation across the brain, supporting a predominant somatodendritic localization of 5-HT<sub>2C</sub> receptors. However, in a few instances a lack of correlation between both patterns of signal suggests a possible location on axon terminals. Examples of poor correlation are the

septal nuclei and horizontal limb of the diagonal band (presence of mRNA with apparent absence of binding sites) and the interpeduncular nucleus (presence of binding sites with apparent absence of mRNA).

The cellular localization of 5-HT<sub>2C</sub> receptor mRNA in relation to serotonergic and GABAergic neurons has been studied in the anterior raphe nuclei of the rat (Serrats *et al.*, 2005). In the dorsal and median raphe nuclei, 5-HT<sub>2C</sub> receptor mRNA was not detected in serotonergic cells identified as those expressing 5-HT transporter mRNA. In contrast, 5-HT<sub>2C</sub> receptor mRNA was found in most GABAergic cells, recognized by the presence of glutamic acid decarboxylase mRNA. Such 5-HT<sub>2C</sub> receptor-positive GABAergic neurons were mainly located in the intermediolateral and lateral portions of the dorsal raphe and lateral part of the median raphe. The present data give anatomical support to a previous hypothesis that proposed a negative-feedback loop involving reciprocal connections between GABAergic interneurons bearing 5-HT<sub>2A/2C</sub> receptors and 5-HT neurons in the dorsal raphe and surrounding areas. According to this model, the excitation of GABAergic interneurons through these 5-HT<sub>2C</sub> (and 5-HT<sub>2A</sub>) receptors would result in the suppression of 5-HT cell firing.

### 5-HT<sub>3</sub> receptors

The 5-HT<sub>3</sub> or 5-HT-M receptor was first identified in the guinea-pig ileum, and then more widely in the peripheral nervous system (PNS) (Gaddum and Picarelli, 1957). The presence of 5-HT<sub>3</sub> receptors in the brain has been a matter of controversy. With the development of adequate ligands this issue has been settled, as both membrane binding and autoradiography were successfully performed in brain tissue with compounds such as [<sup>3</sup>H]ICS-205930 (Waeber *et al.*, 1988b), [<sup>3</sup>H]ondansetron (Kilpatrick *et al.*, 1987), [<sup>3</sup>H]zacopride (Parker *et al.*, 1996) and its iodinated analog [<sup>125</sup>I]DAIZAC (Hewlett *et al.*, 1999) following initial successful binding in neuroblastoma glioma cells (Hoyer and Neijt, 1987) that suggested indeed the presence of 5-HT<sub>3</sub> receptors in the CNS. There are currently five 5-HT<sub>3</sub> receptor subunits that have been cloned (Maricq *et al.*, 1991; Belelli *et al.*, 1995; Davies *et al.*, 1999; Dubin *et al.*, 1999; Hanna *et al.*, 2000), and the receptor is a pentamer like, for example, nicotinic acetylcholine receptors. We will limit ourselves to the 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> subunits, which appear to form the basis of the functional heteromeric channel (Davies *et al.*, 1999). The radioligands used do not distinguish the subunits. The function of the latter three subunits, 5-HT<sub>3C</sub>, 3D, 3E, is still being debated (Niesler *et al.*, 2003, 2007). On their own they have no channel activity, but are able to heteromerize with

5-HT<sub>3A</sub>, and form functional channels, as is known for 5-HT<sub>3A/3B</sub>. On the other hand, these three subunits seem to be absent from the rodent genome. Since 5-HT<sub>3B</sub> appears to be sparse in the rodent brain (although see below), whereas 5-HT<sub>3C</sub> is possibly present in the brain, and since splice variants of the 5-HT<sub>3A</sub> exist, the situation is far from simple (van Hooft and Yakel, 2003). In addition, 5-HT<sub>3A</sub> and nicotinic receptor subunits can co-assemble and form channels in cell systems, but this has not been demonstrated in the brain (see Chameau and van Hooft, 2006 for discussion and further references).

The highest levels of 5-HT<sub>3</sub> receptor binding sites are within the dorsal vagal complex in the brainstem (Kilpatrick *et al.*, 1989; Pratt *et al.*, 1990). This region comprises the nucleus tractus solitarius, area postrema, and dorsal motor nucleus of the vagus nerve, which are intimately involved in the initiation and coordination of the vomiting reflex; antagonism of 5-HT<sub>3</sub> receptors in these nuclei is therefore likely to contribute to the antiemetic action of 5-HT<sub>3</sub> receptor antagonists. 5-HT<sub>3</sub> receptor expression in the forebrain is low, in most cases less than 40 fmol/mg or even lower. The highest levels outside the brainstem are expressed in regions such as the hippocampus, amygdala and superficial layers of the cerebral cortex. The distribution of 5-HT<sub>3</sub> receptor recognition sites within the forebrain displays species variations. For example, in humans, relatively high levels of 5-HT<sub>3</sub> receptor recognition sites have been located within the caudate nucleus and putamen (Abi-Dargham *et al.*, 1993) whereas low levels are detected within cortical regions (Barnes *et al.*, 1989; Waeber *et al.*, 1989; Abi-Dargham *et al.*, 1993). The majority of species investigated so far, however, express high levels of 5-HT<sub>3</sub> receptors within the hippocampus relative to other forebrain regions (e.g., mouse, rat, man) (Parker *et al.*, 1996).

5-HT<sub>3A</sub> receptor mRNA transcripts are similarly distributed, in the rodent brain, to 5-HT<sub>3</sub> autoradiographic binding (e.g., the piriform cortex, entorhinal cortex, hippocampus) (Tecott *et al.*, 1993). In the hippocampus and prefrontal cortex, mRNA is present in interneurons (Tecott *et al.*, 1993; Puig *et al.*, 2004); this distribution indicates that the 5-HT<sub>3</sub> receptor may mediate the indirect inhibition of excitatory pyramidal neurons via activation of GABAergic interneurons. 5-HT<sub>3</sub> receptor-like immunoreactivity is primarily associated with GABA-containing neurons in the cerebral cortex and hippocampus that often co-localize with CCK (but not somatostatin) (Morales *et al.*, 1996a, 1996b; Morales and Bloom, 1997) or calbindin (but not parvalbumin) in the CA1/CA3 fields (Morales and Bloom, 1997).

Attempts to define the cellular location of the 5-HT<sub>3</sub> receptor expressed in the human basal ganglia indicate that they are not principally located on dopaminergic neurons,

since their density is not influenced by the neurodegeneration within this region associated with Parkinson's disease. However, a significant population of the 5-HT<sub>3</sub> receptors in this region is associated with neurons that degenerate in Huntington's disease (Steward *et al.*, 1993). Huntington's is neuropathologically characterized by the degeneration of neurons that have their cell bodies within the caudate-putamen, which include the GABAergic projection neurons. 5-HT<sub>3B</sub> immunohistochemical labeling has been reported with a selective 5-HT<sub>3B</sub> antibody in the hippocampus (Monk *et al.*, 2001); however, the density of signals is very low and this has not been generally replicated, raising the possibility that 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> do not necessarily co-localize in the brain, and therefore the molecular nature of the brain 5-HT<sub>3</sub> receptor is still in debate. What is not debated, though, is that brain 5-HT<sub>3</sub> receptors can be both postsynaptic (e.g., in the interneurons) and as presynaptic: 5-HT<sub>3</sub> receptor binding in the nucleus of the solitary tract and the dorsal motor nucleus of the vagus is lost upon deafferentiation by nodose ganglionectomy or vagotomy; in addition, these nuclei show no 5-HT<sub>3</sub> mRNA expression, supporting the idea that 5-HT<sub>3</sub> receptors present in these nuclei are presynaptic. It has been reported that 5-HT<sub>3</sub> receptor activation modulates dopamine release, although this action may be indirect, and, directly, GABA release, as documented electrophysiologically in the hippocampus and amygdala. Thus, although 5-HT<sub>3</sub> receptors can be convincingly demonstrated in various brain regions, there is still work to be done to reconcile function and localization as well as subunit composition and co-expression. However, more recently a new antibody has been reported to selectively label 5-HT<sub>3B</sub> subunits in various species, especially mouse and rat (Doucet *et al.*, 2007): in contrast to previous reports, intense labeling was seen in peripheral ganglia (trigeminal, nodose, superior cervical and dorsal root ganglia), where almost 100 percent of neurons expressing 5-HT<sub>3A</sub> subunits were also labeled by anti-5-HT<sub>3B</sub> antibody. 5-HT<sub>3B</sub> immunoreactivity was also found in the rat hippocampus (DG and CA1 layer) and in isolated cortical neurons. Interestingly, both 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> immunoreactivities were increased following nerve lesion, confirming co-localization of both subunits. These data suggest that 5-HT<sub>3</sub> subunit *in situ* hybridization does not inform about heteromeric 5-HT<sub>3A/B</sub> as compared to homomeric 5-HT<sub>3A</sub> receptors in the PNS or CNS of rodents.

### 5-HT<sub>4</sub> receptors

The 5-HT<sub>4</sub> receptor has been known for some time in the gastrointestinal tract (GIT), heart and brain (where it stimulates cAMP production in the mouse colliculi)

(Dumuis *et al.*, 1988). However, it took the development of selective compounds and, eventually, the cloning of the receptor to make its mark (Dumuis *et al.*, 1989; Villalon *et al.*, 1990; Bockaert *et al.*, 1992; Gerald *et al.*, 1995). The 5-HT<sub>4</sub> receptor exists in a number of splice variants (at least 10, and the number is still increasing) which are not equal across species. When referring to autoradiography, we assume that the ligands will bind rather indiscriminately to all splice variants; *in situ* hybridization and RT-PCR have been performed with a number of selective probes in the brain in various species, but a detailed account would be too complex for the current scope. Suffice it to say that 5-HT<sub>4</sub> receptors are prominently expressed in the brain and that, depending on the species studied, various splice variants can be found, although not all are present in brain.

Derivatives of a number of 5-HT<sub>4</sub> receptor ligands have made useful radioligands to map and pharmacologically characterize the 5-HT<sub>4</sub> receptor (e.g., [<sup>3</sup>H]GR113808, [<sup>3</sup>H]RS 57639, [<sup>3</sup>H]BIMU1, [<sup>3</sup>H]prucalopride and especially [<sup>125</sup>I]SB207710). A consistent finding across the species investigated is the presence of relatively high levels of the 5-HT<sub>4</sub> receptor in the nigrostriatal and mesolimbic systems of rat, guinea pig, pig, cow, monkey and man (Grossman *et al.*, 1993; Waeber *et al.*, 1993; Jakeman *et al.*, 1994; Vilaró *et al.*, 1996, 2002, 2005). In rat brain, [<sup>3</sup>H]GR113808 presented prominent binding in the limbic system (islands of Calleja, hippocampus, ventral pallidum, fundus striate, olfactory tubercle, septum and amygdala) and the striato-nigro-tectal pathway. In human brain (Varnas *et al.*, 2003), [<sup>125</sup>I]SB207710 labeled the basal ganglia (caudate nucleus, putamen, nucleus accumbens, globus pallidus and substantia nigra) and the hippocampal formation (CA1 and subiculum) (Figure 1M,O). In the neocortex, high levels were seen in superficial layers, and lower levels in deep cortical layers. 5-HT<sub>4</sub> receptors appear to be largely localized postsynaptically. However, presynaptic localization on terminals of GABAergic (dentate gyrus), dopaminergic and serotonergic neurons is also likely, since the release of these neurotransmitters is modulated by 5-HT<sub>4</sub> agonists.

Vilaró and colleagues (2005) have combined several approaches in rat and guinea-pig brain to study the three variants 5-HT<sub>4(a)</sub>, 5-HT<sub>4(b)</sub>, and 5-HT<sub>4(e)</sub>. They compared the distribution of 5-HT<sub>4</sub> receptors using [<sup>125</sup>I]-SB 207710, as well as that of 5-HT<sub>4(a)</sub>, 5-HT<sub>4(b)</sub> and 5-HT<sub>4(e)</sub> mRNA visualized by *in situ* hybridization (ISHH) (Figure 1L,N) and RT-PCR. In several projection systems (striato-nigral and striato-pallidal pathways, in the hippocampus from dentate granule cells to CA3 habenulo-interpeduncular pathway), 5-HT<sub>4</sub> receptors may be located both somatodendritically and axonally. RT-PCR showed all three variants to be rather widely distributed

(olfactory tubercle, striatum, hippocampus, inferior colliculus, substantia nigra, parietal cortex). 5-HT<sub>4(b)</sub> mRNA was present in all regions examined, whereas 5-HT<sub>4(a)</sub> and 5-HT<sub>4(e)</sub> distribution was somewhat more restricted. In other regions (periaqueductal gray, reticular formation, medial septum, diagonal band), faint ISHH signals are observed for 5-HT<sub>4(a)/4(e)</sub> mRNAs, whereas 5-HT<sub>4(b)</sub> mRNA signals are almost undetectable. Finally, neurotoxic lesions of basal ganglia components in guinea pig (Vilaró *et al.*, 2005) also indicate a location of these receptors on terminals of striatal projection neurons.

Altogether, the brain distribution of 5-HT<sub>4</sub> receptors is compatible with a role for these receptors in memory and emotion (Compan *et al.*, 2004; Lucas *et al.*, 2007).

### 5-HT<sub>5A</sub> receptors

The 5-HT<sub>5A</sub> and 5-HT<sub>5B</sub> receptors are still considered to be 'orphans', since there is no clear function attached to these receptors and 5-HT<sub>5B</sub> does not exist in humans (Grailhe *et al.*, 2001), because the human gene is interrupted by stop codons. Further, even the coupling of the receptors is not firmly established.

The distribution of 5-HT<sub>5A</sub> receptors was studied using *in situ* hybridization (Pasqualetti *et al.*, 1998), specific antibodies and receptor autoradiography, although no selective and adequate radioligand is available. Carson and colleagues (1996), using 5-HT<sub>5A</sub>-selective antibodies, found immunoreactivity in astrocytes, and reported increased 5-HT<sub>5A</sub> mRNA levels in reactive gliosis. However, more recent studies have not found 5-HT<sub>5A</sub> receptors in astrocytes. Oliver and co-workers (Oliver *et al.*, 2000) and others (Doly *et al.*, 2004) reported on the distribution of 5-HT<sub>5A</sub> immunoreactivity in brain and spinal cord. 5-HT<sub>5A</sub>-ir was expressed in various layers of the cerebral cortex, in the hippocampus, septum, amygdala and hypothalamus, mostly in axon terminal fields from the median raphe. Furthermore, the suprachiasmatic nucleus, basal ganglia, diagonal band nuclei, amygdala (especially central, basolateral and lateral nuclei), ventral pallidum, entorhinal and cingulate cortices and paraventricular hypothalamus were also identified.

Radioligand binding was performed on WT and 5-HT<sub>5A</sub>-knock-out mouse brains (Waeber *et al.*, 1998; Grailhe *et al.*, 1999). [<sup>125</sup>I]LSD, a high-affinity ligand for the 5-HT<sub>5A</sub> receptor, was used in the presence of adequate spiperone and clozapine concentrations to block 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>6</sub>, 5-HT<sub>7</sub>, and dopamine receptor binding. High levels of [<sup>125</sup>I]LSD binding sites were found in the olfactory bulb and medial habenula of WT mice, with lower densities in the neocortex, hippocampus and caudate putamen. In contrast, 5-HT<sub>5A</sub>-knock-out mice displayed little specific

binding except in the medial habenula (possibly 5-HT<sub>5B</sub> binding). In spite of these data, the function of the 5-HT<sub>5</sub> receptors remains elusive in the absence of selective tools or genetic links to disease. Functional studies performed with the only selective 5-HT<sub>5A</sub> antagonist, SB-699551-A, suggest an autoreceptor role for the 5-HT<sub>5A</sub> receptor in guinea-pig raphe nucleus (Thomas *et al.*, 2006). Furthermore, Serrats *et al.* (2004) reported that 5-HT<sub>5B</sub> receptor mRNA was co-localized with that of the 5-HT transporter primarily in the dorsal raphe, suggesting a possible autoreceptor role for 5-HT<sub>5B</sub> as well.

### 5-HT<sub>6</sub> receptors

The existence of the 5-HT<sub>6</sub> receptor has been suspected in striatum and in neuroblastoma cells, where a positively cAMP coupled 5-HT receptor with atypical pharmacology was described and confirmed when the 5-HT<sub>6</sub> receptor was cloned. It seems that this receptor is brain-specific.

5-HT<sub>6</sub> receptor mRNA is largely confined to the central nervous system, although low levels may be found in the stomach and adrenal glands (Ruat *et al.*, 1993; but see also Monsma *et al.*, 1993; Mengod *et al.*, 2006). High levels of 5-HT<sub>6</sub> receptor mRNA are consistently detected within the striatum (caudate nucleus) of rat, guinea pig and human (Ruat *et al.*, 1993; Mengod *et al.*, 2006). Relatively high levels are also present in the olfactory tubercle, nucleus accumbens and hippocampus.

Subsequently, receptor distribution was studied using the selective antagonist [<sup>125</sup>I]SB-258585 (Roberts *et al.*, 2002), which shows high specific binding when used in autoradiographic studies in rat: very prominent signals light up in the caudate putamen, nucleus accumbens, islands of Calleja, olfactory tubercle and choroid plexus. Moderate levels were present in the hippocampus, cerebral cortex, thalamus, hypothalamus and substantia nigra; and low levels in the globus pallidus, cerebellum, other mesencephalic regions and the rhombencephalon.

Immunocytochemistry was also used to map 5-HT<sub>6</sub> receptor distribution (Gerard *et al.*, 1997; Hamon *et al.*, 1999): dense signals were found in the frontal, entorhinal and piriform cortices, nucleus accumbens, cerebellum, caudate-putamen, hippocampus (dentate gyrus and CA1), olfactory tubercle and islands of Calleja. Moderate staining was detected in other cortical zones, the taenia tecta, substantia nigra, oculomotor nucleus, red nucleus, motor trigeminal nucleus and facial nucleus. The septum, globus pallidus, hypothalamus, colliculi and raphe nuclei were negative. These immunohistochemical studies, including electron-microscopic investigations, have shown prominent dendritic localization of the 5-HT<sub>6</sub> receptor. The striatal binding sites may be on intrinsic GABAergic

or cholinergic neurons, or on terminals of projection neurons from the thalamus or cerebral cortex.

Given the prominent expression in the striatum, it was suspected that 5-HT<sub>6</sub> receptors interact with dopamine transmission. A number of antipsychotics have high affinity for 5-HT<sub>6</sub> receptors. However, 6-OHDA lesions in the substantia nigra and striatum produced no significant changes in [<sup>125</sup>I]SB-258585 binding in any brain region examined, suggesting that 5-HT<sub>6</sub> receptors are not located on dendritic, somatic or terminal elements of dopaminergic neurons. Similarly, the depletion of serotonergic innervation via 5,7-dihydroxytryptamine did not affect 5-HT<sub>6</sub> receptor expression, suggesting that 5-HT<sub>6</sub> receptors are not presynaptic autoreceptors (Bourson *et al.*, 1998).

### 5-HT<sub>7</sub> receptors

The 5-HT<sub>7</sub> receptor has been known for some time in the cardiovascular or GIT system, and was originally termed 5-HT<sub>1</sub>-like, since it has rather high affinity for 5-CT and, to some extent, for 8-OH-DPAT (Hoyer *et al.*, 1994). When cloned, it was realized that although the pharmacology is very similar to that of the so-called 5-HT<sub>1</sub>-like receptor, it is obvious that 5-HT<sub>7</sub> and any of the 5-HT<sub>1</sub> receptor subtypes have very little in common structurally; in addition, 5-HT<sub>7</sub> receptors essentially mediate cAMP stimulation, in contrast to 5-HT<sub>1</sub> receptors (Hoyer *et al.*, 1994).

The 5-HT<sub>7</sub> receptor has a number of splice variants, and attempts have been made to quantify the expression of these using *in situ* hybridization or PCR (To *et al.*, 1995). Initially, based on the high affinity of 5-HT<sub>7</sub> receptors for 5-CT, autoradiographic studies were performed using [<sup>3</sup>H]5-CT in the presence of blocking concentrations of ligands interacting with 5-HT<sub>1</sub> receptors (Vanhoenacker *et al.*, 2000). More recently, [<sup>3</sup>H]SB-269970 has been described as a highly selective radioligand for 5-HT<sub>7</sub> receptors, and autoradiographic studies could be performed (Varnas *et al.*, 2004b). In various species, including human brain, 5-HT<sub>7</sub> binding is found in anterior thalamus and the hippocampus (dentate gyrus) at high levels. Other regions expressing intermediate levels are the septum and hypothalamus (suprachiasmatic nucleus SCN), other hippocampal regions (CA1, CA2), the anterior cingulate and other cerebral cortical areas (in pyramidal cells and on GABAergic neurons), some amygdala and brainstem nuclei and basal ganglia, and Purkinje cells in the cerebellum. Similar findings have been reported in rat and guinea pig (To *et al.*, 1995; Gustafson *et al.*, 1996), and are in agreement with mRNA distribution (Vanhoenacker *et al.*, 2000). The receptor is also found, as expected, in the GIT and vascular smooth muscle, and

a few sympathetic ganglia, as well as in the cerebral and meningeal circulation. The localization in the SCN may relate to sleep-modulating effects of 5-HT<sub>7</sub> ligands, and it has become evident that a number of antipsychotics act as inverse agonists at 5-HT<sub>7</sub> receptors. However, it is not established that a 5-HT<sub>7</sub> antagonist may be an antipsychotic in its own right.

With respect to the distribution of the isoforms of the 5-HT<sub>7</sub> receptor, large tissue-specific differences in the splicing of pre-mRNA within a species are not apparent (Heidmann *et al.*, 1997, 1998). However, the relative abundance of the 5-HT<sub>7(b)</sub> receptor isoform displays marked differences between rat (low) and human (high) tissues. Altogether, 5-HT<sub>7</sub> receptors are expressed in the brain, and protein and mRNA distribution appear to correlate. Immunocytochemistry has also been used to map 5-HT<sub>7</sub> receptor distribution (Moyer and Kennaway, 1999; Geurts *et al.*, 2002; Doly *et al.*, 2005) with good results.

## Conclusion

5-HT receptors (and the 5-HT transporters as well as tryptophan hydroxylase, not addressed here) are present in the brain, in general, in rather similar manners across species. 5-HT receptors are clearly main players in various physiologic and pathophysiologic situations either directly or indirectly following long-term effects of selective serotonin or noradrenalin reuptake inhibitors on their transporters. Not all 5-HT receptors have found their niche, and there are odd exceptions, such as 5-HT<sub>5B</sub>, which does not exist in human, or 5-HT<sub>1e</sub>, whose functional protein is not produced in rodents. There are still question marks regarding other receptors such as 5-HT<sub>2B</sub>, whose presence and function in the brain is not resolved. Additional complexity relates to apparent existence of the numerous editing variants of the 5-HT<sub>2C</sub> receptors, or the many splice variants of 5-HT<sub>4</sub> or 5-HT<sub>7</sub> receptors whose distribution and specific function cannot be studied easily due to the lack of tools. There is also evidence that mRNA and protein levels do not need to match, and even their distribution can be rather different between cell bodies and terminals. The bigger challenge appears to be 5-HT<sub>3</sub> receptor subunits, for which mRNA may not be easily found in the brain or even peripheral nervous system, whereas antibodies may detect significant levels of protein. Another challenge is cellular co-localization, for which the tools must be exquisitely selective and sensitive before conclusions can be drawn. Finally, receptor distribution studies need to reach the subcellular level if we are to understand whether receptor heteromers are produced *in situ*, as has been suggested in recombinant systems, being of the same family

(e.g., 5-HT<sub>1B/1D</sub>), or more complex situations such as dopamine/5-HT receptor heteromers, or channels that combine 5-HT<sub>3</sub> and nicotinic receptor subunits. The diversity of combinations appears endless, and we have not addressed the function of accessory proteins, which may well explain a number of pathologic conditions depending on whether receptor addressing may function normally or not.

# Measuring Serotonin Activity *in vivo* in the Brains of Animals and Humans

Charles A. Marsden\*

*School of Biomedical Sciences, University of Nottingham Medical School, Nottingham, UK*

**Abstract:** Serotonin research has resulted in the identification of up to 14 receptors in the brain. A real challenge is to develop experimental strategies and methods that can be used to investigate the role of these receptors in the integrated function of the serotonergic systems in the animal and human brain *in vivo*. There are now methods available that can measure *in vivo* functional changes in extracellular serotonin (microdialysis, voltammetry). However, with microdialysis temporal and spatial resolution is limited, and while voltammetry has the capability to improve on both these limitations, development of suitable readily usable electrodes is still required. The serotonin transporter and some serotonin receptors can be monitored using positron emission tomography (PET), but work is still required to develop new and better ligands for other receptors. Tryptophan depletion studies can be effectively used to investigate altered serotonergic function in subjects with an underlying trait dysfunction, though its ability to be used to investigate the role of serotonin in normal function remains debatable. Magnetic resonance imaging techniques, in particular fMRI combined with selective pharmacological interventions, offer an exciting new approach to investigating the interactions between serotonin pathways and other neurotransmitters in integrated behavioral responses.

**Keywords:** microdialysis, voltammetry, positron emission tomography, PET, tryptophan depletion, functional magnetic resonance imaging, fMRI, pharmacological MRI, phMRI.

## Introduction

The advances made over the past 20 years with the identification of a multiplicity of serotonin receptors (presently numbering 14) found in the brain associated with the wide and diverse serotonergic innervation, derived from a few midbrain neurones, provides a particular challenge to those neuroscientists and pharmacologists interested in receptor function. This interest is not just confined to the identification of the function of individual receptors, though this offers considerable possibilities in terms of drug development, but also to their role in the integrated function of the serotonergic systems in the brain. Examples of the latter include the complex interaction between the 5HT<sub>1A</sub> and 5HT<sub>2C</sub> receptors in the pathways responsible for psychosis (Geyer and Vollenweider, 2008) or aversive behaviors (Millan, 2006), or the role of 5HT<sub>2C</sub> in feeding and neuroendocrine function (Lucki, 1998). Such studies are now becoming possible with the development of a range

of methodologies that have allowed investigation of the mechanisms that regulate serotonergic function *in vivo* and during behavior. With the current emphasis on so-called translational research, it is important that we have methodologies that can be applied to both animal and human studies.

This short chapter will consider the principles underlying the methods and provide selected examples of their application from a historical viewpoint. The major *in vivo* methods to be considered are those that measure serotonin release (microdialysis and voltammetry), receptors and transporters (positron emission tomography (PET) imaging) and integrated neuronal function in response to pharmacological and behavioral interventions (pharmacological and functional magnetic resonance imaging (phMRI, fMRI)). Other methods that allow manipulation of serotonin levels in the brain (tryptophan depletion studies) or indirect measurement of receptor function in the brain (neuroendocrine markers) will also be briefly discussed. Emphasis will be placed on the way these methods can be used in the non-anesthetized and preferably freely moving animal (or human).

## Measurement of serotonin release (efflux) *in vivo*

### Microdialysis

The quest to develop a method by which transmitter release could be measured *in vivo* has been active for many years, with the original approaches based on the push–pull cannula (Myers and Beleslin, 1970), but it was the development of the hollow fiber microdialysis probe (Ungerstedt and Pycock, 1974) linked to a highly selective high performance liquid chromatography (HPLC) separation combined with the excellent sensitivity of the electrochemical detector (ECD) (Keller *et al.*, 1976) that made expectation a reality. While the initial microdialysis studies concentrated on the measurement of striatal dopamine due to the abundance of dopamine in the striatum and the relative ease at targeting that brain area (Zetterstrom *et al.*, 1983), it was not long before the method was applied to serotonin. Early studies concentrated on drug-induced changes and, importantly, studies showing that a selective agonist of the 5-HT<sub>1A</sub> receptor reduced serotonin release (Marsden, 1985; Sharp *et al.*, 1989) – a finding supported by complementary *in vitro* studies (Middlemiss and Hutson 1990), and one that resulted in the identification of the 5-HT<sub>1A</sub> receptor as the somatodendritic autoreceptor (Sprouse and Aghajanian, 1987). With improvements in technology the microdialysis method was soon adapted for use in freely moving animals, and consequently to behavioral situations. One of the early behavioral microdialysis studies demonstrated increased hippocampal serotonin release when rats were exposed to an aversive environment (elevated plus maze) (Wright *et al.*, 1992), thus providing *in vivo* functional evidence for the importance of serotonin in the acute response to aversion.

Microdialysis is a catheter-based sampling technique in which the catheter essentially mimics the function of a capillary blood vessel (for review, see Li *et al.*, 2006). The tip of the catheter (probe) is formed by a dialysis membrane of known molecular size (normally 15 kDa cut-off) that is continuously perfused with artificial cerebrospinal fluid (CSF) and when implanted in a brain area allows unbound molecules to transfer from the extracellular space around the probe into the artificial CSF, which is then collected and analyzed. As mentioned already, serotonin in the perfusate can then be measured by HPLC-ECD or alternatively by mass spectrometry (MS). The method is not just restricted to the measurement of neurotransmitters (amines and amino acids) and can be applied widely to other molecules important in brain/neuronal function (glucose, lactate), as well as sampling brain levels of administered drugs. Importantly, microdialysis can be used in humans as well as animals, though

human brain studies are obviously limited to very special circumstances; however, in contrast, it has been widely used in humans to monitor blood metabolites. In one such study changes in intravenous serotonin were measured in cancer patients in response to cisplatin, and comparisons made between the effects of two 5-HT<sub>3</sub> antagonists on the cisplatin response (Castejon *et al.*, 1999). In another recent microdialysis study skin serotonin was shown to increase in patients with burn injuries, indicating that it may have a role in local vascular control and formation of edema (Samuelsson *et al.*, 2008).

It is important to understand that microdialysis does not truly measure neurotransmitter release, as the diameter of the probe (0.2–0.5 mm) is far greater than the size of a synapse. What is really measured is transmitter overflow or efflux into the extracellular space, which occurs following release and subsequent reuptake or metabolism, and a more precise description of what microdialysis measures are changes in extracellular levels rather than transmitter release.

Microdialysis offers many advantages, including relative ease of use in freely moving animals, a high level of specificity and a wide range of substances that can be successfully detected. There are, however, negative aspects to the method. One important factor is the size of the probe, in terms of both its external diameter (0.2–0.5 mm) and the length of dialysis membrane (normally 3–4 mm) required to obtain sufficient serotonin for detection by the assay methods available. The main limitation, however, is the time resolution of the method, which is measured in minutes per sample and generally ranges from 5 to 30 minutes, depending on the sensitivity of the assay for the transmitter under investigation and the brain area being sampled. For serotonin, the time resolution is generally in the 15- to 30-minute range rather than the 5- to 15-minute range. This contrasts with the time resolution of the changes in neuronal activity and transmitter release observed following neuronal activation by physiological or behavioral stimuli, which will be in the range of milliseconds to seconds. While this problem is not too serious when using microdialysis to look at the time effects of drugs on serotonin release, which occur over a comparable period of time to the temporal resolution of the probe – and indeed the effects of drugs are often cumulative – it is more of an issue in behavioral studies aimed at identifying key serotonergic triggers in a behavioral sequence. The issue of time resolution has been one of the driving forces in the attempts to develop voltammetric probes suitable for the detection of serotonin.

Microdialysis has been used in a wide range of pharmacological and behavioral situations to gain understanding of the alterations in release of serotonin. It is beyond the scope of this review to discuss these studies in detail, as

they will be covered elsewhere in this volume. It is clear, however, that serotonin release is influenced by a wide range of external stimuli and, depending on the nature of the stimulus, the effect may be stimulus-specific as well as regional-specific (Lucki, 1998). From a brief look at some of the early publications using microdialysis to measure extracellular serotonin, it is clear that changes are observed which result from non-specific behavioral activation (Reuter *et al.*, 1997), but there are also numerous studies showing increases in limbic areas (hippocampus, prefrontal cortex) in response to environmental stressors such as exposure to the elevated plus maze (Wright *et al.*, 1992), footshock (Fulford and Marsden, 1998), conditioned emotional response (Muchimapura *et al.*, 2002; Figure 1) and contextual fear conditioning (Wilkinson *et al.*, 1996). In the isolated reared rat, which shows hyper-responsiveness to novelty and stress, the increase in serotonin in the hippocampus in response to footshock or fear conditioning fails to occur (Muchimapura *et al.*, 2002; Figure 1), while the serotonergic response in the nucleus accumbens is greatly enhanced (Fulford and Marsden, 1998). These results suggest that the forebrain changes in extracellular serotonin in response to external stressors are associated with coping with the stressor, thus supporting the view that drugs such as the serotonin selective reuptake inhibitors (SSRIs) act in anxious states by enhancing serotonergic inhibition of the response to stress. It is also interesting to note that while acute stressors, as described above, increase extracellular serotonin in limbic areas, more prolonged stress – such as forced swimming (Kirby *et al.*, 1995), aggression and drug withdrawal states (Parsons *et al.*, 1995) – reduce extracellular serotonin. In a recent study we have shown that short-term (10-minute) restraint stress increases hippocampal extracellular serotonin, while 1-hour restraint stress produces no change or a decrease in the extracellular levels, indicating that the serotonergic response to stress in limbic areas is time-dependent.

More recent interest in serotonin has focused on the role of specific (5-HT<sub>1A</sub>, 5-HT<sub>4</sub> and 5-HT<sub>6</sub>) receptors in cognition (for review, see King *et al.*, 2008). For example, 5-HT<sub>6</sub> receptor antagonists have been shown to prolong retention and enhance consolidation of information using a range of tests. Microdialysis studies that have measured not only extracellular serotonin but also glutamate and GABA have helped to understand the serotonergic mechanisms involved in the pro-cognitive effects of these drugs. Administration of the 5-HT<sub>6</sub> antagonist SB-271046 increased extracellular glutamate levels in the frontal cortex (Dawson *et al.*, 2000), while agonists such as WAY-181187 and WAY-208466 increased extracellular GABA in the frontal cortex as well as the amygdala, hippocampus and striatum. Immunohistochemical studies

**Figure 1** Graph showing the effect of administration of the 5-HT<sub>1A</sub> agonist 8-OHDPAT on the electrophysiological recordings from dorsal raphe neurons of the rat while measuring extracellular serotonin and 5-HIAA in the frontal cortex with a Nafion®-coated electrochemical electrode. Note the decrease in firing due to activation of the somatodendritic autoreceptors in the dorsal raphe and the associated decrease in serotonin release but no change in 5-HIAA, indicating that measurement of the metabolite is not a good index of release. Data modified from Crespi *et al.* (1990).

have located the 5-HT<sub>6</sub> receptors on GABA neurons, and this, combined, with the glutamate and GABA information, indicates that activation of 5HT<sub>6</sub> receptors increases GABA release which then inhibits glutamate release, so administration of the antagonists prevents the increase

in inhibitory GABA release, leading to improved cognitive function. Increasingly we need to look at the integrated picture of the interactions between different neurotransmitters to gain understanding, rather than just concentrating on changes in one transmitter. The use of multiple-probe microdialysis offers the opportunity to do this type of study in the individual animal, particularly when combined with suitable behavioral paradigms.

### Voltammetry

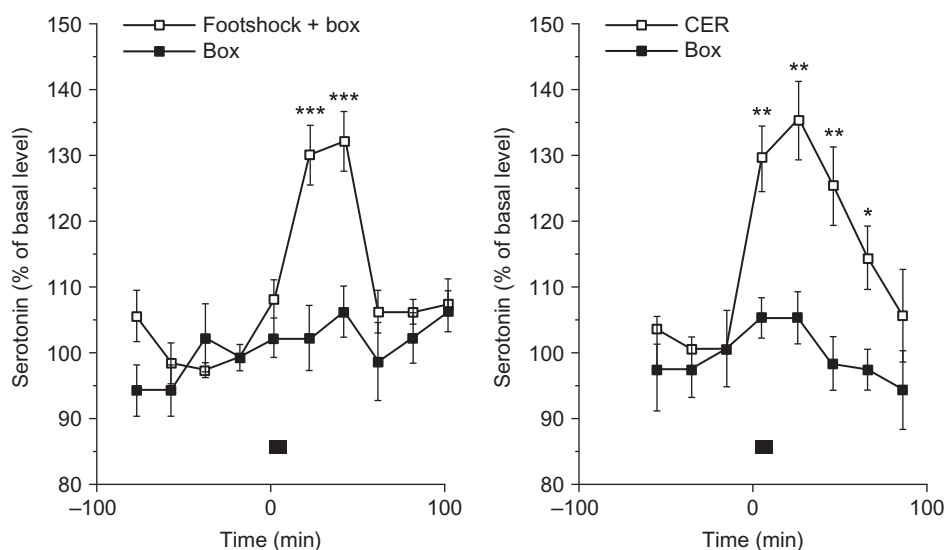

The idea of developing fine voltammetric probes that could be implanted into specific brain areas and used to measure electroactive neurotransmitters such as dopamine, noradrenaline and serotonin (Figure 2) came from Ralph Adams's inventive laboratory at the University of Kansas (Adams, 1976). The concept is to scale down the electrochemical detector used with HPLC and then apply a suitable potential to catalyze the oxidation of serotonin before measuring the current produced (Figure 2). However, unlike the HPLC-ECD methodology there is no separation of the individual amines prior to their oxidation, and as they oxidize at rather similar potentials to each other, and most importantly also at a similar potential to ascorbic acid, this raised important issues about the specificity of the signals detected. Ascorbic acid is abundant in the brain, and its release from neuronal and non-neuronal cells in the brain is associated with transmitter release, and it soon became apparent that the signals

detected in the early voltammetric studies and attributed to either dopamine or serotonin (Conti *et al.*, 1978) were contaminated by the oxidation of ascorbate (Gonon *et al.*, 1980).

Since those early days with voltammetry, several important advances have been made to the methods of scanning (fast scan cyclic voltammetry, chronoamperometry, constant potential amperometry) as well as development of suitable electrodes and biosensors (for review, see Robinson *et al.*, 2008) such that it is now possible to measure dopamine release in real time (Phillips *et al.*, 2003) using electrodes (tip diameters of 10  $\mu\text{m}$  or less) that can simultaneously make electrophysiological recordings while also monitoring behavior (Cheer *et al.*, 2007). Advances in the area of serotonin have not been so rapid due to its rather more complex oxidation pattern, which results in a build-up of oxidation products on the electrode surface, leading to a loss of the functional properties of the electrode. Secondly, the oxidation profile is similar to that of dopamine and ascorbate, again creating difficulties with selectivity. Two approaches to this problem have been adopted. The first approach was to coat the electrodes with Nafion®, which allows penetration of the amines, but not their acid metabolites or ascorbate, to the electrode surface (Gerhardt *et al.*, 1984). Early studies indicated that this could be a way of developing an electrode with sufficient sensitive and selectivity to measure serotonin (Crespi *et al.*, 1988). Studies with these electrodes have demonstrated that serotonin measured using voltammetry relates to changes in serotonergic neuronal function, but this is not the case with the

**Figure 2** Electrochemistry of catechols and indoles. When this is performed at the surface of a suitable electrode so that it acts as the oxidizing agent, the release of electrons is measured in the form of current. The amount of current produced is directly proportional to the number of molecules oxidized. The problem is to separate the different molecules that can be oxidized, including abundant levels of ascorbate. In recent years this process has been achieved by improved scanning methodology and the development of biosensors using Nafion®. Full details of the electrochemistry of all molecules that might be detected using electrochemical electrodes are given in Robinson *et al.* (2008).

**Figure 3** The effect of mild footshock and conditioned emotional response (CER) on hippocampal serotonin measured in the dorsal hippocampus of the rat. Mild footshock (0.4 mA) ( $n = 6/\text{group}$ ) was given for 1 second every minute for 10 mins using a conditioning box. For the CER study, the footshock was given as described on day 1 in the conditioning box and then the rat was returned to its home cage; 24 hours later the rat was placed back in the conditioning box but without shock being applied so that the response observed is to the contextual cue. The point at which mild footshock or CER was performed is indicated by the black square at the base of the graph. Microdialysis samples were collected using concentric probes at 20-min intervals from the CA1 region of the hippocampus. The levels of serotonin in the dialysates were measured using HPLC with electrochemical detection. Note the marked increase in serotonin in response to both mild footshock and CER compared to the controls that were just exposed to the conditioning box without footshock. The data have been adapted from Muchimapura *et al.* (2002).

major serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) (Crespi *et al.*, 1990; Figure 3). Another approach has been to maximize the fast scan cyclic voltammetric approach, developed to measure dopamine, to meet the requirements of serotonin. This has been done successfully to measure serotonin release *in vitro* from brain slices (Bunin *et al.*, 1999), and very recently for *in vivo* measurement of serotonin release in the Red Nucleus of the rat (Hashemi and Wightman, 2008).

The development of selective and sensitive electrodes or biosensors based on electrochemical properties needs to be advanced, as they offer real advantages over the microdialysis method in terms of understanding the precise role of serotonin in specific behavioral events. While advances have been made, we are not yet at the point where voltammetric electrodes are widely available for chronic behavioral studies. Voltammetric electrodes have the advantage of real-time resolution combined with improved tip diameter. Comparing the scale of an implanted microdialysis probe and a voltammetric electrode is like comparing a tree trunk with a twig.

### Measurement of receptors and transporters *in vivo*

SPECT and PET are the only methods available that allow visualization of receptors and transporters in the

living animal or human and which offer the possibility of investigating changes associated with physiological, pharmacological and pathological events. The key to successful PET imaging is the identification of suitable receptor and transporter ligands, and it is really only in the past 10 years or so that suitable ligands for the serotonin transporter (SERT) and now some serotonin receptors (e.g., 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub>) have been identified. Suitable ligands must be able to enter the brain, have very high selectivity for the specific site targeted, show low non-specific binding (otherwise this can result in false positive information) and show an appropriate rate of release from the specific binding sites.

### SERT tracer ligands and PET applications in animals and humans

Early studies employed [<sup>123</sup>I]-βCIT with single photon emission computed tomography (SPECT), but there were issues with its specificity as it had a similar affinity for both the dopamine and serotonin transporters and it also had relatively low sensitivity, which prevented location of SERT in some brain regions of interest – the anterior cingulate cortex, for example (Bhagwagar *et al.*, 2007). The original PET SERT ligand was *trans*-1,2,3,5,6,

10- $\beta$ -hexahydro-6-[4-(methylthio)phenyl]pyrrolo-[2,1-a]isoquinoline (+)- $^{11}\text{C}$ -McN5652 ( $^{11}\text{C}$ McN5652), but this too has issues associated with its use due to the level of non-specific binding and the kinetics of the compound (Szabo *et al.*, 1999; Buck *et al.*, 2000). A more recent addition is 3- $^{11}\text{C}$ -amino-4-(2-dimethylaminomethylphenyl-sulfanyl)benzonitrile ( $^{11}\text{C}$ -DASB) (Wilson *et al.*, 2000), which appears to have both high affinity and selectivity for SERT *in vitro* and *in vivo*.

Szabo *et al.* (2002) and Frankle *et al.* (2004) have compared the two ligands,  $^{11}\text{C}$ McN5652 and  $^{11}\text{C}$ -DASB, using PET, in both the baboon, under various experimental conditions (control, ecstasy (MDMA) treatment and paroxetine treatment), and humans. The results found a high correlation between the binding of the ligands and the known regional levels of SERT, with preferential binding in areas known to have high SERT. The binding of both ligands was reduced by MDMA treatment in a comparable manner, and paroxetine treatment altered both the kinetics and metabolism of the two ligands, with marked displacement from areas with high endogenous SERT binding. There were, however, differences between the two tracers that indicated preference for  $^{11}\text{C}$ -DASB, as it has higher brain activity, a faster removal rate and provided greater contrast between subcortical and cortical regions.

PET studies on SERT have provided important information regarding the long-running issue as to whether MDMA produces long-term loss of serotonergic function in the human in a similar manner to that reported in animals. Studies using  $^{11}\text{C}$ McN5652 demonstrated a loss of serotonergic terminals (McCann *et al.*, 1998; Buchert *et al.*, 2003), but these studies had various limitations in terms of methodology – for example, the Buchert study used the cerebellum as the reference region to control for non-specific binding, though it is now known that SERT is present there. More recently McCann and co-workers (McCann *et al.*, 2005) repeated their study using both  $^{11}\text{C}$ McN5652 and  $^{11}\text{C}$ -DASB, and again found generalized loss of SERT in the MDMA users, as well as a good correlation between the two tracers. The question remains as to whether these results, based on 23 subjects, all of whom reported using MDMA on at least 25 occasions but not within 2 weeks of scanning, can be generalized to all MDMA users. One problem, common to all drug-abuse studies, is that MDMA users do not necessarily restrict their drug use to that single drug, and interactions between drugs may occur in terms of serotonergic effects. Furthermore, it is not clear what the clinical significance is of the loss in SERT. The assumption is that loss of SERT reflects a loss of serotonergic nerve terminals and consequently a decrease in serotonergic function, a view that supports animal studies showing loss of serotonergic

terminals after MDMA treatment. There is an alternative explanation, as an increase in the number of SERT binding sites, as reported to be associated with seasonal affective disorder, may indicate loss of serotonin in the synaptic cleft due to enhanced reuptake, and so also decreased serotonergic function. Conversely, decreased SERT binding may reflect less reuptake and so increased function when this occurs in the absence of a concomitant loss of terminals. For example, there is debate about what happens to SERT binding, measured by either SPECT or PET, in depressed patients. A recent study, using  $^{11}\text{C}$ -DASB as the tracer, found no change in SERT in brain areas associated with depression (amygdala, anterior cingulate cortex, caudate nucleus, frontal cortex, hippocampus and dorsal raphe nucleus) in recovered male depressed patients, indicating that recurrent depression may not be associated with persistent deficits in SERT. This does not mean that depression is not associated with altered serotonergic function, as there are reported differences in cortical postsynaptic receptors (Bhagwagar *et al.*, 2004, 2006). Clearly changes in SERT measured by SPECT or PET need to be interpreted with care, and should be looked at together with other markers of serotonergic function before reaching a final conclusion.

### ***Ligands for serotonin receptors for use with PET***

A key area for future development of tracer ligands for use with PET will center on serotonin receptors and, while the present discussion will be restricted to 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors, other receptors such as the 5-HT<sub>6</sub> receptor are obvious future targets.

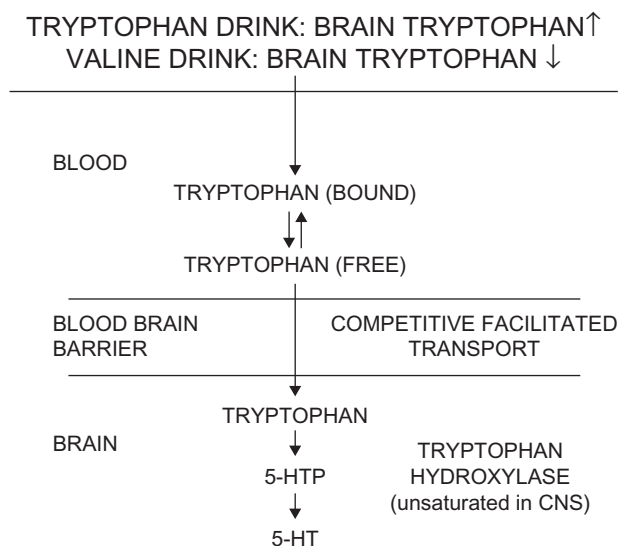

The availability of selective antagonists for the 5-HT<sub>1A</sub> receptor had a substantial impact on research into the function of this receptor (Forster *et al.*, 1995) which was then translated into the development of new radiotracers for this receptor. The first was [18F]-FCWAY (Neumeister *et al.*, 2004a), and although this compound gave reliable signals in subcortical areas it was less successful in cortical areas, as bone retained the fluoride signal (Carson *et al.*, 2003). A ligand with excellent delineation and precision for PET use is  $^{11}\text{C}$ WAY-100635 (Pike *et al.*, 1996). This radiotracer has been successfully used to show persistent reductions in 5-HT<sub>1A</sub> postsynaptic receptors in specific brain areas in recovered depressed patients (Bhagwagar *et al.*, 2004) and both pre- and postsynaptic receptors in patients with panic disorder (Nash *et al.*, 2008). This radiotracer offers real promise for future PET studies in both animals and humans.

The 5-HT<sub>2A</sub> receptor has generated interest in terms of its possible importance in depression, as well as in the mode of action of antipsychotic drugs and hallucinogenic

and psychotic behavior (Geyer and Vollenweider, 2008). Two radiotracer ligands that target this receptor are  $^{18}\text{F}$ -Setoperone and  $[^{11}\text{C}]$  MDL 100,907. The latter compound appears to have suitable properties, as it shows high brain uptake, good contrast of the PET images, and does not produce radiolabeled metabolites. It demonstrates good binding potential to the receptor, and is recommended as the best PET ligand for the 5-HT<sub>2A</sub> receptor at present (Hinz *et al.*, 2007). Interestingly, PET studies in both animals (Hirani *et al.*, 2003) and humans (Talbot *et al.*, 2004) have shown that binding of the ligand to the 5-HT<sub>2A</sub> receptor is independent of changes in synaptic serotonin concentrations, which suggests it can be used to monitor 5-HT<sub>2A</sub> function without having to consider the effect of changes in serotonin levels.

### Tryptophan depletion and the measurement of serotonin function

The special nature of the synthesis of serotonin in the brain offers a unique way to alter serotonergic function in both animals and humans. The enzyme tryptophan hydroxylase, which converts tryptophan to 5-hydroxytryptophan, is unsaturated at normal brain tryptophan concentrations; thus the synthesis of serotonin in the brain is dependent upon tryptophan availability and its uptake by the brain. Tryptophan uptake into the brain is by the large neutral amino acid transport system for which tryptophan competes with other essential amino acids for entry into the brain. It is possible to deplete plasma tryptophan and reduce its uptake by the brain by administering to subjects a tryptophan-free amino acid mixture of essential amino acids that compete with tryptophan for transport into the brain across the blood–brain barrier (Figure 4). Preclinical studies have shown that this results in decreased plasma tryptophan levels and decreases in brain tryptophan, serotonin and its metabolite 5-hydroxyindole acetic acid (5-HIAA) in the rat (Gessa *et al.*, 1974; Curzon, 1979). The same procedure in the human has been shown to decrease plasma tryptophan and the levels of this amino acid as well as those of 5-HIAA in cerebrospinal fluid (CSF) (Williams *et al.*, 1999). These data clearly point to tryptophan depletion reducing brain serotonergic function; however, a note of caution is needed, as a recent microdialysis study in the rat found that while a tryptophan-free amino acid mixture reduced plasma tryptophan, there was no change in the extracellular levels of either serotonin or dopamine in the prefrontal cortex, indicating no change in serotonergic function and thus that reduced serotonergic function may not fully explain the behavioral effects measured both in animals and humans with this method (Van der Plaase *et al.*, 2007).

**Figure 4** Diagram showing the relationship between the plasma tryptophan and brain serotonin (5HT) levels. Plasma tryptophan can bind to plasma protein so only unbound (free) tryptophan is available to the competitive facilitated transporter that transports the essential (large neutral) amino acids across the blood–brain barrier (BBB). Drinks containing no tryptophan and high levels of another large neutral amino acid which compete for the transporter, such as valine, will reduce levels of tryptophan in the brain and thus reduce the synthesis of serotonin in the brain.

One potential explanation is that serotonergic function is only reduced by tryptophan depletion when there is an underlying trait abnormality of serotonergic function, but not when serotonergic function is normal (as in the experiment described above). Indeed, the most striking results with tryptophan depletion in humans have been found in remitted depressed patients, when tryptophan depletion results in a transient return of the symptoms during the period of tryptophan depletion (Smith *et al.*, 1997; Neumeister *et al.*, 2004b), but not in control subjects with no familial risk of depression (Moreno *et al.*, 1999). These findings support the idea of a trait serotonergic abnormality in depressed patients, and it has been suggested that tryptophan depletion may be clinically useful in identifying individuals at risk of developing major depression (Moreno *et al.*, 2000). Similar conclusions appear to prevail with social anxiety disorder, as patients with this disorder are improved by SSRI treatment but this effect was reversed by tryptophan depletion (Argyropoulos *et al.*, 2004).

There are, however, studies showing changes in cognitive function in healthy young volunteers following tryptophan depletion (Rogers *et al.*, 1999; Schmitt *et al.*, 2000; Finger *et al.*, 2007), as well as activity in the prefrontal cortex measured by fMRI (Rubia *et al.*, 2005).

It remains to be determined whether these effects, in normal subjects, on cognitive functioning can be fully explained by altered serotonergic activity or by some other neural mechanism influenced by tryptophan depletion. Overall, tryptophan depletion studies offer an excellent non-invasive method for identifying disorders with underlying serotonergic dysfunction, but its role in the study of normal serotonergic function remains debatable.

### Neuroendocrine markers and serotonergic function

The importance of various serotonergic receptors in the regulation of pituitary neuroendocrine function is well established, particularly in relation to the HPA axis and the release of cortisol in humans and corticosterone in rats involving 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors (for review, see Fuller, 1996). The same receptors in the hypothalamic paraventricular nucleus are involved with the regulation of prolactin and renin release (Lucki, 1998). This has led to the use of a range of pharmacological agents (SSRIs, 5-HTP, agonists and antagonists, and serotonin releasers as well as tryptophan depletion) with relative selectivity for these receptors to investigate their functional state in various psychiatric disorders by measurement of changes in the peripheral release of the hormones (for review, see Murphy *et al.*, 1996). With the development of improved PET ligands for these receptors, it is becoming increasingly possible to make direct brain measurements rather than indirectly using hormonal markers.

### Measurement of neuronal activity – neural pathways

Electrophysiological techniques have played a key role in understanding the detailed mechanisms involved in serotonin receptor function and their signal transduction pathways, but will not be discussed here because this information is covered elsewhere in this book. The emphasis of this discussion will be on approaches available to look not specifically at serotonergic function, but rather at how manipulation of serotonergic function (for example, using drugs) can lead to changes in brain region activity and neural connections.

Regional metabolic activity as an index of neuronal activity has been very successfully measured using labeled 2-deoxyglucose in conjunction with PET for many years in both controls and patients (Neumeister *et al.*, 2004a). More recently this approach has been superseded by functional magnetic resonance imaging (fMRI), which is non-invasive and provides great potential, as it can be readily linked with cognitive and emotional testing.

It is not the role of this chapter to discuss in detail the potential of fMRI to help our understanding of the ways in which serotonergic neurones interact with other pathways in both normal and abnormal behavior. However, fMRI offers a translational approach, as it can be used both in animals (Steward *et al.*, 2005) and in humans (Northoff *et al.*, 2002; Kemp *et al.*, 2004) to investigate brain regional patterns of neuronal activation and deactivation following drug administration using methods such as Blood Oxygen Level Dependence (BOLD). These drug studies are often referred to as pharmacological MRI (phMRI), to distinguish them from studies (fMRI) using behavioral or cognitive interventions and monitoring the subsequent changes in regional neuronal function. These studies may also incorporate serotonin-selective drugs, for example SSRIs, into their design. An interesting example of this approach is provided by the studies looking at the neural responses of normal subjects and patients to fearful facial expressions of emotion, and how these neural responses are modified by drug treatment (Sheline *et al.*, 2001; Kemp *et al.*, 2004; Chan *et al.*, 2009). These studies have not only identified the brain areas associated with the interpretation of visual emotional stimuli, but also shown greater neural responses to fearful stimuli in depressives and those at risk for depression (Chan *et al.*, 2009). They showed too that SSRI treatment enhanced the neural response to pleasant stimuli and reduced the response to fearful stimulus (Kemp *et al.*, 2004). Neuroimaging of neural activity can play a major role in improved understanding of the pathways involved in the complex interactions between serotonin and other neurotransmitters that drive cognitive and emotional behaviors.

### Conclusions

Considerable effort has been put into the development of methodologies that can be used to monitor serotonergic function during behavior. The results obtained have improved understanding of the function of specific receptors or specific pathways, and benefited the quest for new approaches to the treatment of certain psychiatric disorders in particular. The real challenge is to understand the role of serotonin in the integrated neural pathways that drive behavior, and to do this the methods still require improvement. Measurement of transmitter release requires better time and spatial resolution, while PET methodology needs new ligands for serotonin receptors as yet not detectable by the method. Magnetic resonance imaging will play a central role in the future investigation of integrated function, as it makes it possible to monitor activity within neural pathways involved in cognitive and emotional behavior combined with an ability

to modify responses using serotonergic selective drugs. Such an approach is essential for successful translational studies using both animals and humans.

## Acknowledgements

Studies at Nottingham described in this chapter have been supported by the MRC, BBSRC and Wellcome Trust. We would also like to thank GSK and Lundbeck a/s for financial support.

**Abstract:** We have explored the activity of brain serotonin (5-hydroxytryptamine; 5-HT) neurons in behaving cats exposed to a wide variety of behavioral and physiological conditions. In general, the activity of these neurons is strongly related to spontaneous changes in behavioral state (being highest in active waking and lowest during REM sleep). Across a wide variety of experimental manipulations, the activity of serotonergic neurons was relatively unchanged. This includes dramatic alterations in general physiology. However, one condition, motor activity, strongly affected neuronal activity. A general relationship obtains between level of tonic motor activity and serotonergic neuronal activity across all major groups of serotonergic neurons. Superimposed upon this in some neurons is an additional relationship where a further, often dramatic, activation is seen in association with repetitive, central pattern generator (CPG)-mediated behaviors. The exact nature of this relationship varies both with the specific serotonergic neuronal group and within a particular group. We hypothesize that the primary function of this increased serotonergic neuronal activity is to facilitate behavioral output by coordinating autonomic and neuroendocrine function in association with motor demand, and by a concomitant general suppression of afferent input from sensory processing channels.

**Keywords:** electrophysiological recordings, sleep–wake cycle, stressors, autonomic function, motor activity, hypercapnia, respiration, fatigue.

**Abbreviations:** 5-HT, 5-hydroxytryptamine (serotonin); CCK, cholecystokinin; CNS, central nervous system; CPG, central pattern generator; DRN, dorsal raphe nucleus; EEG, electroencephalogram; EOG, electro-oculogram; EMG, electromyogram; GABA,  $\gamma$ -aminobutyric acid; NCS, nucleus centralis superior; NRM, nucleus raphe magnus; NRO, nucleus raphe obscurus; NRP, nucleus raphe pallidus; REM, rapid eye movement

## Introduction

As the chapters in this volume amply demonstrate, a large variety of approaches have been used to investigate serotonin's functional role(s) in the CNS. Over the past several decades, the confluence of results derived from these varied perspectives (anatomical, physiological, genetic, clinical, behavioral, etc.) has shown the breadth of serotonin's influence on physiology and behavior. Although our laboratory at Princeton University has employed a number of these methodologies over the years, our primary focus has been neurophysiological in nature; specifically, single neuron recordings of brain serotonergic neurons in behaving animals. This chapter represents an overview of

this work, with an emphasis on our more recent studies. (Some of our previous review chapters can be consulted for detailed descriptions of our earlier work in this area – Jacobs and Fornal, 1997a, 1998.)

The overarching goal of our research has been the examination of the behavioral/physiological role of the mammalian CNS serotonin system. Does it have a specific role or roles, or is serotonin a ubiquitous neurotransmitter, like GABA or glutamate, exerting effects on virtually all brain processes, and thus serving no specifiable behavioral or physiological function? Is there a general theory of CNS serotonin function which could account, at least in part, for the broad array of data on this topic?

The primary tool that we employed in our work was measuring the electrical activity of individual serotonergic neurons ('single unit recordings') in unanesthetized, freely behaving domestic cats (*F. catus*). Our philosophy was to follow leads provided by observing the variations

in neuronal activity that emerged under a diversity of behavioral and physiological conditions.

At the outset, our thinking was guided by certain fundamental facts about brain serotonin. First, the basic plan for the cell bodies of these neurons is conserved throughout the vertebrates. This implies that its function must, to some degree, be common in the physiology and behavior of fish, amphibians and reptiles as well as mammals, including primates. Second, virtually all of the cell bodies of serotonergic neurons are found in the brainstem, on or near the midline. This suggests a somewhat stronger involvement in basic processes, especially those associated with axial functions, such as controlling the trunk and proximal limb muscles. Finally, these neurons and their processes are among the first to develop during ontogeny. All of this suggests that the central serotonin system subserves basic or fundamental functions within the CNS.

In an attempt to establish generalizations about serotonin's role, we examined the activity of serotonergic neurons throughout the neuraxis. The clusters of brain serotonergic neurons can be divided into two major groups. The rostral or mesencephalic group contains two primary nuclei which supply most of the serotonin to the forebrain: the nucleus centralis superior (NCS) and the dorsal raphe nucleus (DRN). The caudal or medullary group contains three primary nuclei which supply most of the serotonin to the brainstem and spinal cord: the nucleus raphe magnus (NRM), the nucleus raphe obscurus (NRO), and the nucleus raphe pallidus (NRP).

### Basic neuronal characteristics

Our recording technique employing chronically implanted microwires allows us to record the activity of the same neuron over long periods of time and despite active, gross movements. Many presumed 5-HT neurons have a distinctive 'neuronal signature' that makes them unique in the CNS and allows them confidently to be identified on-line as serotonergic. They discharge in a slow (typically 1–6 Hz) and highly regular manner. This clock-like activity is the manifestation of an endogenous pacemaker. These neurons also possess an unusually long-duration action potential (2–3 ms). These neuronal characteristics appear to be somewhat universal since they are: (1) observed in *in vitro* preparations, under anesthesia, and in behaving animals; (2) seen in the several species in which this has been examined; and (3) found in the various brainstem groups of 5-HT neurons (Jacobs and Azmitia, 1992).

Although the preponderance of serotonergic neurons manifest these characteristics ('typical'), brain serotonergic neurons with other electrophysiological features ('atypical') have also been identified: see work from the

laboratories of Sakai (Sakai and Crochet, 2001), Beck (Beck *et al.*, 2004), Sharp (Hajos *et al.*, 1995) and Urbain (Urbain *et al.*, 2006). Unfortunately, there has been little attempt to examine the response of these 'atypical' serotonergic neurons across varied behavioral and physiological conditions, other than the sleep–wake–arousal cycle. Furthermore, studies of these neurons have been limited, almost exclusively, to the DRN. Finally, whereas our studies have been carried out in domestic cats, with the exception of the studies of Sakai the rest of this work has been conducted in laboratory rats.

### Sleep–wake–arousal cycle

In the quiet waking state in the cat, the activity of DRN 5-HT neurons is slow (~3 spikes/s) and regular, characteristic of the unmodulated operation of an endogenous pacemaker (Jacobs and Fornal, 1991). During an aroused state or in response to sensory stimuli, neuronal activity can be increased 30–50 percent above the quiet waking level. The most dramatic changes in the activity of 5-HT neurons occur during sleep. As animals become drowsy and enter slow-wave sleep, neuronal activity slows to approximately 50 percent of the quiet waking level and loses its regularity. Finally, during REM sleep, the activity of most brain 5-HT neurons declines dramatically, in many cases falling to zero. This general pattern of activity across the sleep–wake–arousal cycle displayed by 5-HT neurons in the DRN is also seen, with some variation, in the other major groups of brainstem 5-HT neurons: NCS, NRM, NRO and NRP (Figure 1) (Jacobs and Fornal, 1991).

### Response to stressors

As a starting point for our research program, we reasoned that it would be informative to examine the activity of brain 5-HT neurons under extreme and varied conditions. Thus, we studied neuronal responses in cats exposed to a number of strong environmental and physiological stimuli. Accordingly, the activity of 5-HT neurons in the DRN, NCS or NRM was examined while cats were exposed to: a heated environment or a pyrogen; drug-induced increases or decreases in blood pressure; insulin-induced hypoglycemia; phasic or tonic painful stimuli; systemic injections of morphine; loud noise; physical restraint; or a natural enemy (dog) (see Jacobs and Fornal (1991) for details). Despite the fact that all of these conditions evoked strong behavioral responses and/or physiological changes indicative of sympathetic activation, none of them significantly activated 5-HT neuronal activity in the DRN, NCS or NRM beyond the level typically seen

**Figure 1** Activity of 5-HT neurons across the sleep-wake-arousal cycle. Panel A shows mean firing rates for a group of DRN and NRO/NRP neurons. In general, the spontaneous firing rate of medullary raphe neurons is higher than that of mesencephalic raphe neurons during comparable behavioral states. Panel B shows the activity of a typical medullary 5-HT neuron across the sleep-wake-arousal cycle. Note the positive relationship between neuronal activity and the level of tonic motor activity/muscle tone in the nuchal EMG. EEG, electroencephalogram; EOG, electro-oculogram; EMG, electromyogram.

during an undisturbed active waking state (studies of the response of caudal medullary 5-HT neurons – in NRO and NRP – to autonomic nervous system perturbations are described in the following section).

A couple of examples from this series of studies illustrate this point. The activity of DRN 5-HT neurons was examined in response to both increased ambient temperature and pyrogen-induced fever, stimuli eliciting opposite thermoregulatory responses (Fornal *et al.*, 1987). Neuronal activity remained unaffected as ambient temperature was increased from 25°C to 43°C. Following prolonged heat exposure, cats displayed intense continuous panting, relaxation of posture, and a progressive rise in body/brain temperature (range 0.5–2.0°C), yet no change in 5-HT neuronal activity occurred. In a parallel study, a synthetic pyrogen (muramyl dipeptide) was administered systemically, resulting in increased body/brain temperature within

30 minutes and lasting for approximately 6 hours. The peak elevation of body temperature was typically 1.5–2.5°C, yet, once again, no change in neuronal activity was observed.

A large and relatively consistent body of evidence implicates central 5-HT in analgesia, especially those 5-HT neurons localized in the NRM and projecting to the dorsal horn. Accordingly, we examined the activity of NRM 5-HT neurons in behaving cats exposed to a variety of phasic or tonic painful stimuli. No change in neuronal activity was produced by these stimuli relative to the discharge rate during an undisturbed active waking baseline (Auerbach *et al.*, 1985). There was also no change in 5-HT neuronal activity in response to the systemic administration of morphine, in a dose that produced analgesia. These results have been confirmed in studies reporting that identified serotonergic NRM neurons in the rat were not activated by painful stimuli eliciting the withdrawal

reflex or by analgesic doses of morphine (Potrebic *et al.*, 1994; Gao *et al.*, 1998).

In summary, these data indicate that mild to relatively strong stressors, drawn from a number of different environmental and physiological categories, do not significantly perturb brainstem serotonergic neurons. It is important, however, to emphasize that stressors do activate the serotonergic system, but that they do so no more than other non-stressful, activating conditions. One way of reconciling this with the behavioral and physiological processes with which 5-HT has been implicated is to invoke the concept of conjunctive activation. For example, 5-HT released during feeding may exert a role in satiety only in the presence of increased release of cholecystokinin (CCK). Employing this line of reasoning, 5-HT released in reaction to exposure to stressors would exert a different effect than it does during feeding because it now interacts with corticosterone rather than CCK. In addition, this acknowledges that such interactions may occur only in specific brain areas (e.g., hypothalamus versus hippocampus). In an important demonstration of this principle, Stutzman and colleagues (Sutzmann *et al.*, 1998) found that the electrophysiological effect of 5-HT on amygdala neurons in rats was abolished in the absence of corticosterone.

### Autonomic function

The activity of medullary 5-HT neurons (NRO and NRP) and their relation to autonomic function is of special interest because these neurons have extensive projections to the intermediolateral cell column of the thoracic spinal cord, where they make connections with sympathetic preganglionic neurons, including those that innervate the adrenal medulla (Bacon *et al.*, 1990). Reciprocally, 5-HT medullary neurons receive direct synaptic inputs from the rostral ventrolateral medulla (Zagon, 1993), the primary source of sympathetic activity. A number of studies have shown that 5-HT exerts predominantly an excitatory influence on sympathetic outflow (McCall, 1984; Huangfu *et al.*, 1994). Therefore, medullary 5-HT neurons may serve a homeostatic role in regulating arterial blood pressure and heart rate, body temperature, and blood glucose concentrations.

In this context, we examined the activity of medullary 5-HT neurons during manipulations of the cardiovascular system by producing transient alterations in arterial blood pressure (and sympathetic activity) and by intravenous administration of vasoactive drugs (Martin-Cora *et al.*, 2005). The activity of 5-HT NRO/NRP neurons was not significantly altered in response to phenylephrine (a vasoconstrictor) or sodium nitroprusside (a vasodilator), at doses which elicited marked reflex bradycardia

and tachycardia, respectively. Furthermore, no significant changes in neuronal activity were observed after systemic administration of hydralazine, a direct long-acting vasodilator, despite prolonged reflex activation of the sympathetic nervous system, as indicated by sustained increases in heart rate and plasma norepinephrine levels. Acute venous hemorrhage, up to 22.5 percent of estimated total blood volume, also had no effect on the activity of NRO/NRP neurons, despite the fact that plasma catecholamine levels were significantly elevated by this manipulation. Overall, these results do not support a direct role of 5-HT NRO/NRP neurons in the reflex alterations in sympathetic (and parasympathetic) outflow evoked by these cardiovascular manipulations. This suggests that any involvement of 5-HT medullary neurons in cardiovascular regulation is mediated independently of cardiovascular afferent activity.

We have also used insulin-induced hypoglycemia to preferentially activate the sympathoadrenal system (Martin-Cora *et al.*, 2002). Administration of insulin (2–4 IU/kg, i.v.) produced a 50 percent decrease in blood glucose and a near eight-fold increase in plasma epinephrine levels. Surprisingly, the discharge rate of 5-HT NRO/NRP neurons was *reduced* by approximately 40 percent after insulin administration. The subsequent administration of glucose reversed the effect of insulin on blood glucose, plasma epinephrine and neuronal activity. Thus, firing rate was directly correlated with blood glucose and, more importantly, inversely correlated with plasma epinephrine levels. Since medullary 5-HT neurons are thought to subserve a sympathoexcitatory role, these results contradict what would be predicted for these cells. However, animals treated with insulin also displayed diminished muscle tone and signs of muscle weakness, which closely paralleled the decreases in neuronal activity observed after insulin administration. Thus, the effect of systemic insulin on 5-HT neuronal activity may be related to changes in motor output rather than to changes in sympathetic outflow (see below).

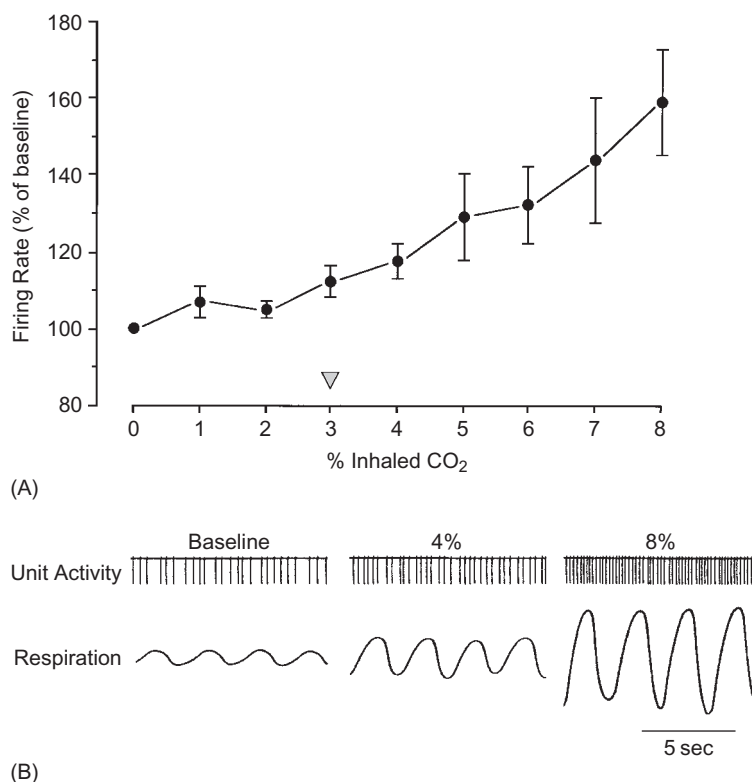

Medullary 5-HT neurons may also participate in the central control of respiration through connections with respiratory-related structures in the pons/medulla and phrenic motoneurons (see Chapter 2.10 in this volume). Recent electrophysiological studies have shown that rat medullary 5-HT neurons recorded *in vitro* are highly sensitive to changes in CO<sub>2</sub> and/or pH, suggesting that they may function as ‘central chemoreceptors’ to modulate respiratory output (Wang *et al.*, 2001). To determine whether medullary 5-HT neurons are chemosensitive *in vivo*, we examined the responses of these neurons to hypercapnia (Veasey *et al.*, 1995), a potent respiratory stimulus which augments ventilatory output by activating primarily central, and to a lesser extent peripheral, chemoreceptors. In support of a role in respiratory modulation, a subset (22 percent) of NRO/NRP neurons

was activated in association with increased respiration induced by inhalation of carbon dioxide (Figure 2). The magnitude of the neuronal response was correlated positively with the fraction of inspired  $\text{CO}_2$  and was related to ventilatory motor output, specifically inspiratory amplitude. The threshold level of  $\text{CO}_2$  for producing a significant increase in firing rate was about 3 percent, suggesting relatively high chemosensitivity. During sleep, the responsiveness of these neurons to systemic  $\text{CO}_2$  stimulation was greatly reduced or abolished, and paralleled the diminished ventilatory sensitivity to  $\text{CO}_2$ . These data suggest that diminished activation of 5-HT neurons during sleep may contribute to the reduced motor responses to hypercapnia and therefore may play an important role in sleep-related breathing disorders, such as sleep apnea and sudden infant death syndrome (SIDS). Additionally, a small subset (25 percent) of 5-HT neurons in the DRN was also activated by hypercapnia (Veasey *et al.*, 1997). Some of these cells, which are known to project to the cervical spinal cord, may directly influence respiratory motor output. Although these studies provide evidence that 5-HT neurons in both the rostral and caudal raphe nuclei are sensitive to hypercapnia under physiological conditions, it is

not clear whether the neuronal responses were intrinsic or synaptically mediated by other cells involved in respiratory control, as this would require blockade of afferent inputs to address. Furthermore, although hypercapnia can induce profound effects on cerebral blood flow, cardiac output and arterial pressure, 5-HT neurons in general are unresponsive to alterations in cardiovascular activity, as discussed above. Therefore, it is unlikely that the observed neuronal responses to increased  $\text{CO}_2$  are mediated by secondary changes in cardiovascular function induced by hypercapnia. Consistent with our findings in awake animals that some 5-HT neurons are activated by hypercapnia, systemic  $\text{CO}_2$  stimulation in cats has been reported to induce *c-fos* expression (a marker of neuronal activation) in the caudal raphe (Larnicol *et al.*, 1994); however, double-labeling experiments are needed to positively identify these cells as serotonergic.

### Motor activity

Initial clues that there might be an important relationship between 5-HT neuronal activity and motor activity

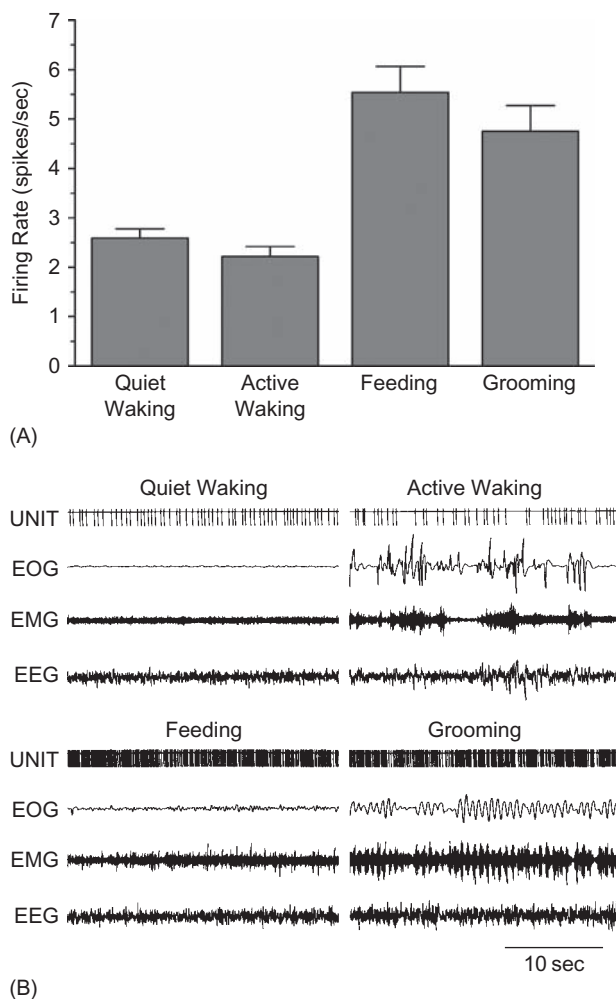

**Figure 2** Activation of medullary 5-HT neurons during increased respiration induced by inhalation of carbon dioxide ( $\text{CO}_2$ ). Panel A shows the concentration–response curve to  $\text{CO}_2$  for a group of responsive cells. The arrowhead denotes the threshold concentration of  $\text{CO}_2$  for producing a significant increase in mean firing rate. Panel B shows the activity of one of these cells, along with respiration, at baseline, when the cat was breathing room air, and then at 4 and 8 percent  $\text{CO}_2$ . Note the progressive increase in respiratory depth and firing rate of this cell. Adapted from Veasey *et al.* (1995).

came from our early experiments where motor output was drastically altered by using pontine lesions to block the atonia of REM sleep (Trulson *et al.*, 1981) and by microinjecting carbachol into the pons to produce atonia during waking (Steinfels *et al.*, 1983). These data indicated that the activity of rostral 5-HT neurons was more closely related to the level of tonic motor activity than to the behavioral 'state' of the animal.

In recent experiments, we have observed more specific relationships between 5-HT neuronal activity and *phasic* motor function. When cats engage in a variety of types of CPG-mediated oral-buccal activities, such as chewing/biting, licking or grooming, approximately one-fourth of DRN 5-HT neurons increase their activity by as much as two- to five-fold (Figure 3) (Fornal *et al.*, 1996). In contrast, the rest of the 5-HT neurons in this nucleus maintain their slow and rhythmic activity. These increases in neuronal activity often *precede* the initiation of movement by several seconds, but they invariably terminate coincident with the end of the behavioral sequence. Equally impressive is the fact that even brief (1–5 s) spontaneous pauses in these behaviors are accompanied by an immediate decrease in neuronal activity back to baseline levels, or below. During a variety of other non-rhythmic episodic or purposive movements, even those involving oral-buccal responses such as yawning, no increase, or even a decrease, in neuronal activity is seen. During dramatic attentional shifts, such as those occurring during orienting movements in response to imperative stimuli, the activity of DRN 5-HT neurons may fall silent for several seconds (Fornal *et al.*, 1996). This occurs in association with large eye movements, turning the head toward the stimulus, and suppression of any other ongoing behaviors.

Based on these data demonstrating a strong relationship between DRN 5-HT neurons (those that innervate fore-brain) and motor activity, we explored these same issues for NRO and NRP neurons (those that innervate the spinal cord). In contrast to mesencephalic 5-HT neurons, where only a subgroup is activated during CPG-mediated behaviors, virtually all medullary serotonergic neurons are activated under at least some of these conditions (Veasey *et al.*, 1995). The magnitude of activation, however, is much less (i.e., 50–100 percent above baseline versus 100–400 percent above baseline for the DRN). In this context, it may be important to note that the basal, quiet waking discharge rate of medullary serotonergic neurons is approximately twice that of mesencephalic serotonergic neurons (5–6 vs 2–3 spikes/s). There also appears to be at least some degree of response specificity for these neurons. Thus, virtually all medullary serotonergic neurons are activated during treadmill-induced locomotion (Figure 4), but only subgroups are activated during increased respiratory output induced by hypercapnea, or during chewing/

**Figure 3** Activation of DRN 5-HT neurons during spontaneous feeding and grooming behavior. Panel A shows mean firing rates for a group of oral-buccal related cells during feeding and grooming in relation to active and quiet waking baseline firing rates. Panel B shows the activity of one of these cells across all four behavioral conditions. The firing rate of this cell was increased approximately three-fold during feeding and grooming, as compared to waking. The rhythmic nature of the grooming can be seen in the EOG and nuchal EMG traces. Also, note the decrease in unit discharge rate and regularity during active waking (cat moving) as compared to quiet waking. EEG, electroencephalogram; EOG, electro-oculogram; EMG, electromyogram. Adapted from Fornal *et al.* (1996).

licking. Many of these individual neurons are activated in association with more than one of these motor activities. Initial indications are that, like the rostral 5-HT neurons, at least some of these caudal 5-HT neurons can be activated by somatosensory stimulation. It is still not clear whether there is a preferential body area (e.g., trunk or limbs versus head) where such stimulation is most effective. Finally, *unlike* DRN 5-HT neurons, NRO and NRP

(A)

Serotonin Unit Activity

(B)

**Figure 4** Activation of medullary 5-HT neurons during treadmill locomotion. Panel A shows the relationship between firing rate and speed of locomotion for a group of locomotor-related NRO/NRP cells. Panel B shows the activity of one of these cells during a locomotor trial. This cell increased its firing rate immediately at the onset of running on the treadmill (speed = 0.4 m/s). Neuronal activity returned immediately back to, or just below, baseline levels when the treadmill was stopped. Adapted from Veasey *et al.* (1995).

neuronal activity is not suppressed during orienting responses. This may reflect a lack of involvement of the spinal cord-projecting neurons in functions associated with cognition, such as attention.

During treadmill-induced locomotion the magnitude of increased neuronal activity showed a strong positive correlation with the speed of running (from 0.25 to 0.85 m/s) (Veasey *et al.*, 1995). A few cells even displayed an increased discharge that was in phase with the step cycle. Finally, the excitatory neuronal response during treadmill locomotion was precisely coincident with the onset of the treadmill, and remained stable for a given speed. When the treadmill was stopped, unit activity returned immediately to, or just below, baseline. This suggests that the firing rate of these neurons is tightly coupled to motor activation rather than autonomic activity, such as heart rate and blood pressure, which remain elevated after locomotor activity has stopped.

During feeding, two distinct patterns of neuronal activation were observed for NRO/NRP neurons (Veasey *et al.*,

1995). For most cells the increase occurred precisely at feeding onset and was maintained throughout the feeding period. Unit activity abruptly returned to baseline levels with the cessation of eating. Thus, the activity of these neurons appears to be temporally correlated with ingestive behaviors such as chewing, licking or swallowing. In contrast, a few cells demonstrated gradual increases in unit activity during feeding, reaching a plateau 60–80 s after feeding onset, and then only gradually returned to baseline minutes after the termination of feeding. The elevated activity of this subset of neurons is more temporally related to ongoing digestive processes, such as gastric secretion and motility. We hypothesize that these neurons play a role in gastrointestinal function via projections to the parasympathetic preganglionic neurons in the dorsal vagal complex.

Finally, when DRN neurons were examined under identical conditions, none were activated during treadmill-induced locomotion or cold exposure (Veasey *et al.*, 1997; Martin-Cora *et al.*, 2000), but some were activated during carbon dioxide-induced hyperpnea (Veasey *et al.*, 1997).

## Fatigue

Physical exercise cannot be maintained indefinitely, and eventually fatigue will terminate motor output. Traditionally, peripheral factors, such as intramuscular depletion of energy substrates (e.g., glycogen) or accumulation of metabolic byproducts (e.g., lactic acid), have been thought to be responsible for fatigue, although there is now clear evidence that changes within the central nervous system can contribute to fatigue (Davis and Bailey, 1997). Besides its direct role in motor output, it is becoming increasingly clear that the debilitating fatigue associated with some chronic diseases (e.g., chronic fatigue syndrome and multiple sclerosis) also appears to be mainly of central origin (Davis and Bailey, 1997; Swain, 2000), and is moreover an important factor in clinical depression (Swain, 2000).

Central fatigue consists principally of a failure to maintain full motor unit recruitment and/or optimal motor unit discharge for muscle force production (Sale, 1987), and has been linked to an inadequate descending drive from the motor cortex (Gandevia *et al.*, 1996). Serotonin is the neurotransmitter most often implicated in human forms of fatigue and in animal experiments examining exercise-induced fatigue (Newsholme and Blomstrand, 1995; Davis and Bailey, 1997; Davis *et al.*, 2000). Recent work in our laboratory suggests that 5-HT neurons in the NRO and NRP may play an important role in various aspects of central fatigue (Fornal *et al.*, 2006). These neurons are known to facilitate both the excitability and

the recruitment of  $\alpha$ -motoneurons (Jacobs and Fornal, 1997b). As described above, in the awake cat the activity of these 5-HT neurons is suppressed in relation to diminished motor capacity (i.e., experimentally induced muscle hypotonia/atonina, and muscle weakness). These findings have led us to hypothesize that diminished activity of the descending medullary 5-HT system may be an important component of central fatigue. During prolonged treadmill locomotion (0.4 m/s for 30–60 min), we have found that the activity of some NRO/NRP 5-HT neurons progressively decreases from baseline levels (Fornal *et al.*, 2006). An additional more rapid decline is often observed immediately after the treadmill is turned off, at the time the cat can no longer keep pace – i.e., ‘fatigue’. Neuronal activity in these animals gradually returns to baseline within 30–60 min. During this recovery period, activity can be reactivated momentarily by turning on the treadmill, indicating that increased motor output is still capable of driving these cells, albeit at a reduced rate. Preliminary evidence suggests that these effects of sustained locomotor activity may be unique to NRO/NRP 5-HT neurons, inasmuch as DRN 5-HT neurons do not show this decline. We hypothesize that during prolonged locomotor activity a central mechanism is activated inhibiting the output of medullary 5-HT neurons, which in turn leads to a disfacilitation of  $\alpha$ -motoneuron excitability (and autonomic dysregulation), thus contributing to the development of fatigue.

Some of the factors that might be responsible for this fatigue-related decrease in 5-HT neuronal activity and, thereby, contribute to the development of fatigue are: (1) whole body carbohydrate stores which become depleted during prolonged exercise (glucose administration to animals exhibiting signs of fatigue may reverse these effects); (2) a progressive increase in core body temperature, which is thought to limit physical output (cooling or antipyretic drugs may therefore reverse these alterations in 5-HT neuronal activity); and (3) hypoxia, which may be important in the decreased 5-HT neuronal activity seen during fatigue.

## Discussion

A general relationship exists between level of tonic motor activity and 5-HT neuronal activity across all groups of 5-HT neurons that we have studied. Superimposed upon this in some neurons is an additional relationship in which a further, often dramatic, activation is seen in association with repetitive, CPG-mediated behaviors. The exact nature of this relationship varies both with 5-HT grouping (e.g., locomotor-related NRP neuronal activity versus grooming-related DRN neuronal activity) and within a particular group (e.g., respiratory-related and feeding-related NRP neuronal activity). The primary function

of this increased 5-HT neuronal activity in association with tonic and repetitive motor output is to coordinate autonomic and neuroendocrine function in association with the existing motor demand, and to suppress activity in most sensory information processing channels (Prochazka, 1989; Nelson, 1996).

There are several reasons for believing that the facilitation of motor output by 5-HT is general in nature. First, 5-HT neuronal activity is generally tonically elevated during the execution of a particular behavior, suggesting that 5-HT is facilitating the ‘behavior’ rather than a particular motor act or muscle group that is a component of the behavior. Secondly, the distribution of 5-HT axon terminal innervation of the brainstem and spinal cord is consistent with the involvement of 5-HT in patterned movement employing gross skeletal muscles rather than movements using finer or more discrete muscles, such as those controlling the eyes or the digits. Thus, in the spinal cord there is a denser input to the medial portion of the ventral horn, where axial motoneurons serving the trunk and limbs are found, compared to the lateral portions, where distal motoneurons serving paws and digits are found (Steinbusch, 1981). Thirdly, there is evidence that spinally projecting medullary 5-HT neurons collateralize at various levels of the cord, suggesting a broad relationship to motor activity (Allen and Cechetto, 1994). Finally, the fact that single medullary 5-HT neurons may project to both the intermediolateral column of the spinal cord as well as to the ventral horn suggests an integrative function involving motor and autonomic control (Allen and Cechetto, 1994).

Several important functions may be served by these 5-HT inputs to motor structures. They may smooth motor outputs and may also obviate the need for continuous repetitive excitatory inputs to maintain a continuous output in motor systems. By augmenting weak or polysynaptic inputs, 5-HT may also bring motoneurons to their firing threshold. The anticipation of motor activity by 5-HT neurons suggests that they may serve a ‘priming’, and possibly a conditioning, function for motor output. (It is not yet clear if NRO/NRP 5-HT neurons manifest this anticipatory response, as do DRN 5-HT neurons.) The simultaneous inhibition of irrelevant sensory information processing acts to suppress inputs that might disrupt motor output. Finally, 5-HT’s involvement in autonomic and neuroendocrine regulation serves a support function for the demands associated with changes in the level of motor output, such as increased oxygenation of the blood and redistribution of blood flow to skeletal muscles, or increased glycogenolysis for maintaining a stable glucose supply to the brain.

One of the most impressive aspects of 5-HT’s involvement in motor control is its generality across phylogeny.

There is evidence in a variety of invertebrate species that 5-HT may play a broad, and even integrative, role in such diverse functions as postural control, swimming, and feeding. As discussed above with regards to mammals, there is evidence that in invertebrates 5-HT exerts its effects on behavior at multiple levels: on motoneurons, muscles, CPGs, cardiovascular system, etc. (Kupfermann and Weiss, 1981; Lent, 1985).

In sum, we hypothesize that the primary role of the 5-HT system is to provide coordination of motor, autonomic and sensory processes, which are activated with central motor commands. Furthermore, we believe that *all other* behavioral and physiological functions that have been associated with 5-HT in the brain and spinal cord are derivative of this fundamental relationship.

# Electrophysiology of Serotonin Receptors

Gerard J. Marek\*

*Abbott Laboratories, Neuroscience Development, Abbott Park, Illinois*

**Abstract:** The 14 different serotonin or 5-hydroxytryptamine (5-HT) receptors are widely distributed throughout the central nervous system. Of these 14 serotonin receptors, 13 mediate the slow modulatory action of 5-HT upon fast excitatory or inhibitory effects of glutamate/aspartate and  $\gamma$ -aminobutyric acid (GABA)/glycine, respectively. The presence of different 5-HT receptors in discrete cellular compartments through the neuroaxis allows for an integrated effect of serotonergic neurotransmission on sleep and arousal processes, executive functions of the prefrontal cortex, affective behavior, aggression, learning and memory, and modulation of pain. This is accomplished through specific 5-HT receptors controlling the pace-maker functions of midbrain and brainstem 5-HT-containing neurons which project throughout the neuroaxis, as discussed elsewhere. Different 5-HT receptors are localized on local or projection GABAergic neurons in addition to the different compartments (axons, axon terminals, dendrites, cell bodies) of glutamatergic local or output cells. 5-HT receptors are also present either on other biogenic amine-containing cells or on cells modulating the other biogenic amine-containing cells to modulate the electrophysiological action of norepinephrine, dopamine and acetylcholine throughout the neuroaxis.

**Keywords:** 5-HT receptors, raphe nuclei, prefrontal cortex, hippocampus, striatum, amygdala, autoreceptors, heteroreceptors.

**Abbreviations:** BLA, basolateral amygdala; BNST, bed nucleus of the stria terminalis; EPSC/EPSP, excitatory postsynaptic current/potential; 5-HT, 5-hydroxytryptamine; GABA,  $\gamma$ -aminobutyric acid; IPSC/IPSP, inhibitory postsynaptic current/potential; mPFC, medial prefrontal cortex; mGlu, metabotropic glutamate receptors; MAOIs, monoamine oxidase inhibitors (MAOIs); PFC, prefrontal cortex; SSRIs, selective serotonin reuptake inhibitors; SNRIs, serotonin-norepinephrine reuptake inhibitors; SNpr, substantia nigra pars reticulata; SNpc, substantia nigra pars compacta; STN, subthalamic nucleus; TTX, tetrodotoxin; TCAs, tricyclic antidepressants; VTA, ventral tegmental area; VPM, ventroposterior medial nucleus; VPL, ventroposterior lateral nucleus.

## Introduction

The primary focus of this chapter will be on identifying those 5-hydroxytryptamine (5-HT) receptor subtypes that appear to have the greatest relevance in mediating salient behavioral effects of psychotherapeutic drugs or mediating profound physiological/behavioral changes. A secondary and related focus will be to understand the interplay of different 5-HT receptors within both microcircuits and macrocircuits where multiple 5-HT receptors either interfere with the function of other 5-HT receptors or add to/synergize with the effects of other 5-HT receptors. This chapter will concentrate on the best-characterized 5-HT

receptor subtypes, but will also point out questions and issues which remain unanswered or not addressed.

The transduction pathways used by the fourteen 5-HT receptors is discussed elsewhere. However, there are five 5-HT receptor subtypes that tend to be coupled to  $G_i/G_o$  proteins and are negatively coupled to adenylyl cyclase and the production of cAMP (the 5HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>1D</sub>, 5-HT<sub>1E</sub> and 5-HT<sub>1F</sub> receptors). The 5-HT<sub>5</sub> receptor family may also share these transduction pathways. These receptors tend to have direct inhibitory effects. The 5-HT<sub>3</sub> receptor is the only ionotropic 5-HT receptor, and has direct excitatory effects due to net inward flux of sodium. The 5-HT<sub>2</sub> receptor family members (5-HT<sub>2A</sub>, 5-HT<sub>2B</sub>, 5-HT<sub>2C</sub>) are coupled to  $G_q/G_{11}$  proteins often linked to phospholipase C. These receptors tend to depolarize cells and/or increase the excitability of the cellular compartments in which they are found. The remaining

\*E-mail: gerard.marek@abbott.com

5-HT receptors (5-HT<sub>4</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub>) are coupled to G<sub>s</sub> proteins and a positive modulation of adenylyl cyclase that usually results in direct excitatory effects.

### 5-HT<sub>1A</sub> receptors

The 5-HT<sub>1A</sub> receptor has been one of the most studied members of the serotonin receptor family. This receptor plays a profound role as a somatodendritic autoreceptor on serotonin-containing neurons throughout the midbrain and brainstem. These 5-HT<sub>1A</sub> autoreceptors modulate the pacemaker activity of these neurons in a negative feedback fashion, and are discussed elsewhere (see Chapter 2.1 of this volume). In other regions of the brain, such as the prefrontal cortex, neocortex, hippocampal formation and amygdala, 5-HT<sub>1A</sub> receptors exert direct inhibitory effects. In these different brain regions, the 5-HT<sub>1A</sub> receptors usually are expressed in somatodendritic compartments of principal cells. In the neocortex, 5-HT<sub>1A</sub> receptors are localized to the initial axon segment (or axon hillock) of layer III and layer V pyramidal cells (Azmitia *et al.*, 1996). In the hippocampus, activation of 5-HT<sub>1A</sub> receptors is known to suppress the activity of CA3 pyramidal cells, and this is an effect that is enhanced by many antidepressant drugs (Haddjeri *et al.*, 1998). At a macro-level, activation of 5-HT<sub>1A</sub> receptors reduces the frequency of hippocampal rhythmic slow activity, analogous to the actions of anxiolytic drugs such as benzodiazepines.

#### *Hippocampal 5-HT<sub>1A</sub> receptors: modulation by antidepressant drugs*

Differential changes in presynaptic and postsynaptic 5-HT<sub>1A</sub> receptors appear relevant for understanding how serotonergic function may be modified by antidepressant drugs. The desensitization of somatodendritic 5-HT<sub>1A</sub> autoreceptors was postulated to explain the delayed therapeutic effects of selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs) and monoamine oxidase (MAO) inhibitors (Blier *et al.*, 1986; Chaput *et al.*, 1986; Rueter *et al.*, 1998; Pineyro and Blier, 1999). The activation of somatodendritic 5-HT<sub>1A</sub> receptors in serotonin-containing nuclei decreased the basal firing rate of these neurons and attenuated the enhancement of ambient synaptic 5-HT concentrations throughout the forebrain. However, the enhancement of the inhibitory effects of 5-HT<sub>1A</sub> receptor activation has been found to be a general feature following the subchronic administration (2–4 weeks) of most antidepressant drugs, including tricyclic antidepressants (de Montigny and Aghajanian, 1978), SSRIs (Blier and

de Montigny, 1983; Blier and Bouchard, 1992), SNRIs (Rueter *et al.*, 1998), MAO inhibitors, atypical antidepressants which block 5-HT<sub>3</sub> and 5-HT<sub>2A/2C</sub> receptors (Blier *et al.*, 1984; Haddjeri *et al.*, 1997), electroconvulsive shock (Blier and Bouchard, 1992), lithium (Haddjeri *et al.*, 2000) and 5-HT<sub>1A</sub> receptor partial agonists (Blier and de Montigny, 1987).

Several antidepressant drug combination treatments that have been investigated in clinical practice have also been examined to see whether the drug combination speeds up or increases the maximal enhancement of hippocampal 5-HT<sub>1A</sub> receptor function. The co-administration of mirtazapine and the SSRI paroxetine appeared to accelerate the enhancement of 5-HT<sub>1A</sub> receptor function in CA3 pyramidal cells, developing over a period of 3–4 weeks, in addition to being more effective than either drug alone (Besson *et al.*, 2000). This type of improved therapeutic response in the clinic for the treatment of depressed patients with the combination of either mirtazapine or mianserin has been successful in double-blind, placebo-controlled studies as described elsewhere (Marek *et al.*, 2003). Another medication well known to enhance the clinical effect of antidepressant drugs, especially in treatment-refractory patients, is the addition of lithium carbonate to ongoing treatment with a variety of antidepressant drugs. The addition of lithium to the tricyclic antidepressant (TCA) imipramine, the SSRI paroxetine and the monoamine oxidase inhibitor (MAOI) tranylcypromine has also been found to increase the disinhibition of dorsal hippocampal CA3 pyramidal neurons over that seen with either treatment alone (Haddjeri *et al.*, 2000). Addition of the  $\beta$ -adrenergic receptor antagonist and 5-HT<sub>1A</sub> receptor antagonist pindolol to SSRIs results in greater increases in synaptic 5-HT during the early stages of treatment, and can accelerate the development of an enhanced inhibitory response in CA3 pyramidal cells to 5-HT<sub>1A</sub> receptor activation. Some of the clinical trials suggest that this combination of SSRIs and pindolol for depressed patients may also accelerate the development of therapeutic responses, though this is not without controversy (Artigas *et al.*, 1996). In addition, a 5-HT<sub>1A</sub> receptor agonist and 5-HT<sub>2A</sub> receptor antagonist flibanserin appeared to accelerate both the recovery of firing rate for dorsal raphe neurons with chronic flibanserin administration and the enhancement of the 5-HT<sub>1A</sub> response in CA3 neurons of the rat hippocampus (Rueter and Blier, 1999). Clinical results testing this hypothesis have not been reported.

5-HT<sub>1A</sub> receptors induce postsynaptic hyperpolarizations throughout the limbic forebrain. In CA1 pyramidal cells of the hippocampus, one of the most conspicuous effects of 5-HT<sub>1A</sub> receptor activation is to produce a hyperpolarization by a postsynaptic mechanism. This 5-HT-induced hyperpolarization frequently is

followed by a depolarizing response mediated by 5-HT<sub>4</sub> receptor activation (Andrade *et al.*, 1986; Andrade and Nicoll, 1987; Andrade and Chaput, 1991a; Torres *et al.*, 1996).

### ***Medial prefrontal cortex (mPFC) 5-HT<sub>1A</sub> receptors***

The 5-HT<sub>1A</sub> receptor message ribonucleic acid (mRNA) and binding sites are well distributed throughout the prefrontal cortex and the neocortex (Pompeiano *et al.*, 1992). Estimates from mRNA *in situ* hybridization studies are that ~60 percent of glutamatergic cells and ~25 percent of GABAergic cells express 5-HT<sub>1A</sub> receptor mRNA in the rat prefrontal cortex (Santana *et al.*, 2004). Single-cell polymerase chain reaction (PCR) studies suggested that nearly all prefrontal cortical pyramidal cells (92 percent of 26 cells) expressed 5-HT<sub>1A</sub> receptors (Feng *et al.*, 2001). Activation of 5-HT<sub>1A</sub> receptors results in a hyperpolarization of the cell (Araneda and Andrade, 1991; Ashby *et al.*, 1994; Tanaka and North, 1994). In a sample of layer V mPFC cells, 22 of 90 exhibited a pure hyperpolarizing response while 26 of 90 cells were first hyperpolarized, followed by a depolarization dependent on 5-HT<sub>2A</sub> receptor activation (Araneda and Andrade, 1991). In supragranular cortical layers (layers II–III), 50 percent of 28 sampled pyramidal cells were hyperpolarized by 5-HT with pharmacological characteristics consistent with 5-HT<sub>1A</sub> receptors. With respect to supragranular interneurons, 33 percent of 54 cells were hyperpolarized by 5-HT. About 63 percent of the interneurons with axons restricted to layer I were hyperpolarized by 5-HT. Approximately 50 percent of the 54 cells sampled were depolarized by 5-HT<sub>2A</sub> receptor activation. Thus, 5-HT<sub>1A</sub> receptors exert an important physiological role in prefrontal cortical and neocortical functioning. However, the hyperpolarizing effects of 5-HT<sub>1A</sub> receptor activation appear to work in tandem with the increases in cellular excitability induced by 5-HT<sub>2A</sub> receptors. In this context, behavioral effects such as the suppression by 5-HT<sub>1A</sub> receptor agonists of head shakes induced by serotonergic hallucinogens (which all share in common activation of 5-HT<sub>2A</sub> receptors) are not surprising (Darmani *et al.*, 1990).

### ***5-HT<sub>1A</sub> receptors in the extended amygdala***

In addition to a potential role of prefrontal cortical 5-HT<sub>1A</sub> receptors in mediating behavior relevant to fear, anxiety and aggression, 5-HT<sub>1A</sub> receptors in the extended amygdala may contribute to 'emotional' behavior. A number of studies suggest that activation of 5-HT<sub>1A</sub> receptors suppress neurotransmitter release without altering the

postsynaptic cell when recording from the basolateral nucleus (BLA). One study using a slice preparation found that 8-OH-DPAT and non-selective 5-HT<sub>1A</sub> receptor agonists suppressed excitatory postsynaptic potentials (EPSPs) without altering the resting membrane potential and neuronal resistance (Cheng *et al.*, 1998). These same investigators demonstrated that 5-HT<sub>1A</sub> receptor activation could block the potentiation of excitatory synaptic transmission induced by  $\beta$ -adrenergic receptor activation at a site downstream from cAMP formation (Wang *et al.*, 1999). A somewhat different picture emerged from studies using mechanically dissociated BLA neurons which preserve native presynaptic nerve terminals. 5-HT<sub>1A</sub> receptor activation was found to suppress the frequency of GABA<sub>A</sub>-mediated inhibitory postsynaptic currents (IPSCs) without altering the miniature IPSC amplitude (Kishimoto *et al.*, 2000). Consistent with presynaptic control of neurotransmitter release, activation of 5-HT<sub>1A</sub> receptors has been found to inhibit voltage-dependent calcium currents of the N- and P/Q-types rather than L-type (Lin *et al.*, 2001). A convergence of 5-HT<sub>3</sub> and 5-HT<sub>1A</sub> receptor function was found for mechanically dissociated BLA neurons as the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT was able to suppress the transient facilitation of miniature IPSC frequency induced by the 5-HT<sub>3</sub> receptor agonist mCPBG via an apparent membrane-delimited mechanism (Koyama *et al.*, 2002a).

Not all 5-HT<sub>1A</sub> receptor-mediated responses in the extended amygdala involve inhibition of transmitter release. The anterolateral bed nucleus of the stria terminalis (BNST AL) receives a relatively heavy serotonin projection. Experiments with brain slices suggested that the main action of 5-HT and 5-CT in this area was evoking a hyperpolarization without an alteration in input resistance (Levita *et al.*, 2004). This action of 5-HT and 5-CT was blocked by the relatively selective 5-HT<sub>1A</sub> receptor antagonist WAY100635. Curiously, though, 8-OH-DPAT did not mimic the effects of 5-HT and 5-CT. The importance of these data from a translation to animal behavior is that infusion of 5-CT into the BNST did reduce the acoustic startle response without affecting the animals' general activity level.

### ***5-HT<sub>1A</sub> receptors and the basal ganglia***

5-HT<sub>1A</sub> receptors are also present in motor circuitry. The subthalamic nucleus (STN) is an important structure, since high-frequency stimulation of this brain region is useful in patients with Parkinson's disease. While 5-HT<sub>2C</sub> and 5-HT<sub>7</sub> receptors appear to depolarize or induce inward currents in STN neurons (Xiang *et al.*, 2005), activation of 5-HT<sub>1A</sub> receptors induces hyperpolarization or outward

currents (Stanford *et al.*, 2005; Shen *et al.*, 2007). The globus pallidus (as well as the substantia nigra pars reticulata, SNpr) are innervated by fibers originating from the subthalamic nucleus. While globus pallidus neurons have recently been shown to be depolarized by 5-HT<sub>7</sub> receptor activation, other neurons are hyperpolarized by 5-HT<sub>1A</sub> receptor action through a postsynaptic action (Chen *et al.*, 2008; Hashimoto and Kita, 2008).

### 5-HT<sub>1B</sub> receptors

5-HT<sub>1B</sub> receptors (5-HT<sub>1DB</sub> gene product) play a major role throughout the brain, acting as autoreceptors in the terminals of serotonin-containing cells originating from the brainstem raphe nuclei (see Chapter 2.1). Interestingly, 5-HT<sub>1B</sub> receptors localized at postsynaptic sites relative to serotonin-containing nerve terminals appear to make up the vast majority of 5-HT<sub>1B</sub> receptors throughout the brain, since lesions of raphe neurons do not decrease the number of 5-HT<sub>1B</sub> receptor binding sites. 5-HT<sub>1B</sub> receptors also are used as heteroreceptors in many cells throughout the brain to inhibit the release of neurotransmitters other than serotonin. The striking dissociation between localization of the mRNA and receptor binding for rodent 5-HT<sub>1B</sub> receptors, together with results of lesion studies, have established that this 5-HT receptor is predominantly localized to axon terminals (Boschert *et al.*, 1994).

In the anterior cingulate cortex, 5-HT suppresses electrically-stimulated EPSPs/excitatory postsynaptic currents (EPSCs) recorded from layer V pyramidal cells, and does not have an effect on evoked inhibitory postsynaptic potentials (IPSPs)/IPSCs when stimulating either in the white matter deep to the cortex or in layer V (Tanaka and North, 1993). This 5-HT response was mediated by 5-HT<sub>1B</sub> receptors based on the effects of 5-HT<sub>1B</sub> receptor agonists (TFMPP and CGS12066B) and antagonists (cyanopindolol) as well as agonists and antagonists for other 5-HT and  $\beta$ -adrenergic receptors. This 5-HT<sub>1B</sub> receptor-mediated inhibition of EPSPs was also independent of membrane potential. The absence of direct hyperpolarizing effects of 5-HT<sub>1B</sub> receptor activation coupled with the observation that ~58 percent of pyramidal cells contain 5-HT<sub>1B</sub> receptor mRNA would suggest that cortico-cortical excitatory fibers are modulated by 5-HT<sub>1B</sub> heteroreceptors. 5-HT also suppressed EPSPs evoked by corpus callosum stimulation when recording from layer V pyramidal cells of the mPFC. The pharmacology of these responses appeared to agree with mediation by 5-HT<sub>1B</sub> rather than 5-HT<sub>1A</sub> receptors (Read *et al.*, 1994).

The 5-HT<sub>1B</sub> receptor also plays a physiological developmental role for sensory cortical areas. The

5-HT<sub>1B</sub> receptor is transiently expressed along with the 5-HT transporter in thalamocortical fibers originating in the ventrobasal thalamus and terminating in layer IV. Activation of these 5-HT<sub>1B</sub> receptors reduces the monosynaptic thalamocortical EPSCs evoked by low-frequency stimulation of the internal capsule (Laurent *et al.*, 2002). A clear developmental function for this receptor is suggested by studies of the barrelless monoamine oxidase knockout mice, where inactivation of the 5-HT<sub>1B</sub> receptor then restores the barrels. The expression of the 5-HT<sub>1B</sub> receptor in the thalamocortical pathway of the ventrobasal complex (ventral posterior medial nucleus (VPM)/ventral posterior lateral nucleus (VPL)) and the dorsal lateral geniculate disappears by the end of the second week.

A number of pathways exist where significant mismatches between 5-HT<sub>1B</sub> mRNA and receptor binding are found for the cells of origin and their respective terminal fields. Lesion studies complement the electrophysiological data, suggesting the presence of presynaptic 5-HT<sub>1B</sub> heteroreceptors in these pathways. A variety of extracellular and intracellular studies demonstrate that 5-HT<sub>1B</sub> receptor activation decreases GABA release from striatopallidum terminals and leads to excitation of globus pallidum neurons, consistent with results from striatal kainic lesions (Sari *et al.*, 1999; Querejeta *et al.*, 2005; Hashimoto and Kita, 2008; Rav-Acha *et al.*, 2008). Similarly, a whole-cell patch-clamp recording from the substantia nigra pars reticulata found that 5-HT<sub>1B</sub> receptor activation suppressed evoked GABA<sub>A</sub> receptor-mediated IPSCs (Stanford and Lacey, 1996). Consistent with this electrophysiological study, an antibody recognizing the 5-HT<sub>1B</sub> receptor at the electron microscopic level found immunoperoxidase staining in fine unmyelinated axons and nerve terminals (Sari *et al.*, 1997). Accordingly, neostriatal kainic acid lesions markedly decreased 5-HT<sub>1B</sub> receptor-like immunoreactivity (Sari *et al.*, 1999). Intracellular recordings from the superior colliculus combined with the loss of collicular 5-HT<sub>1B</sub> receptors supported the working hypothesis that 5-HT<sub>1B</sub> receptor activation suppresses glutamate release in the retinocollicular pathway (Mooney *et al.*, 1994, 1996). Activation of 5-HT<sub>1B</sub> receptors also suppresses polysynaptic EPSCs modeling the network activity of CA1/CA1 synapses evoked by electrical stimulation of the stratum radiatum (Mlinar *et al.*, 2003). The CA1 pyramidal neurons project both to other CA1 pyramidal cells in the stratum radiatum and to the subiculum. Knife-cut lesions disrupting the CA1/subicular synapse and CA1 chemical lesions causing a deafferentation of both the CA1/subicular and the CA1/CA1 synapse decrease 5-HT<sub>1B</sub> receptor binding (Amara *et al.*, 1995, 2001). Another region with relatively weak 5-HT<sub>1B</sub> receptor mRNA expression yet strong 5-HT<sub>1B</sub> receptor binding is the subthalamic nucleus, where both

IPSCs and EPSCs are inhibited via activation of 5-HT<sub>1B</sub> receptors.

### 5-HT<sub>1D</sub> receptors

There is relatively little variation in the binding of most ligands to the human gene products of the 5-HT<sub>1D $\alpha$</sub>  and the 5-HT<sub>1D $\beta$</sub>  receptor genes. In contrast, a mutation in the rodent 5-HT<sub>1D $\beta$</sub>  receptor gene (5-HT<sub>1B</sub> receptors) provides pharmacological differentiation for a number of ligands compared to the gene product for the 5-HT<sub>1D $\alpha$</sub>  receptor or 5-HT<sub>1D</sub> receptors. In the rodent, there is a relatively sparse expression of 5-HT<sub>1D</sub> mRNA (5-HT<sub>1D $\alpha$</sub>  gene product) compared to 5-HT<sub>1D $\beta$</sub>  mRNA (Bruinvels *et al.*, 1994). Since the triptans used for migraine treatments activate 5-HT<sub>1D</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>1F</sub> receptors, and 5-HT<sub>1D</sub> receptors tend to have a relatively restricted CNS distribution, most electrophysiology relevant to 5-HT<sub>1D</sub> receptors has concentrated on trigeminal neurons or the nucleus tractus solitarius, and will not be dealt with in detail here (Goadsby and Knight, 1997; Cumberbatch *et al.*, 1999; Hoskin *et al.*, 2004; Jeggo *et al.*, 2007).

### 5-HT<sub>1E</sub> receptors

While the 5-HT<sub>1E</sub> receptor was first cloned in 1992, advancing knowledge for this receptor has been hampered by lack of selective radiotracers and adequate blocking compounds. The mRNA for this receptor is clearly present in the human striatum and layer IV of the visual cortex (Bruinvels *et al.*, 1994). Similarly, quantitative real-time polymerase chain reaction (qRT-PCR) analysis demonstrated 5-HT<sub>1E</sub> mRNA in the guinea-pig brain regions in, in descending order, the hippocampus, olfactory bulb, cortex, thalamus, pons, hypothalamus, midbrain, striatum and cerebellum (Bai *et al.*, 2004). Further advancements in understanding this receptor will require selective receptor agonists, receptor antagonists or small interfering RNA (siRNA).

### 5-HT<sub>1F</sub> receptors

While the 5-HT<sub>1F</sub> receptor is activated by the triptan compounds that have been approved for the treatment of migraine (Ramadan *et al.*, 2003), little work has suggested applications outside of this indication. A novel radioligand, [<sup>3</sup>H]LY334370, has been described for the 5-HT<sub>1F</sub> receptor. Autoradiographic studies demonstrate that this receptor is localized to a number of limbic forebrain-related regions such as layers IV–V of all the neocortical areas examined,

the olfactory bulb, nucleus accumbens, caudate-putamen, parafascicular nucleus of the thalamus, medial mammillary nucleus, the CA3 hippocampal region, subiculum and several amygdaloid nuclei (Lucaites *et al.*, 2005). This localization would suggest that electrophysiological and behavioral studies would be warranted with selective 5-HT<sub>1F</sub> agonists.

### 5-HT<sub>2A</sub> receptors

5-HT<sub>2A</sub> receptors have been implicated in the psychotomimetic effects of serotonergic hallucinogens (Titeler *et al.*, 1988; Aghajanian and Marek, 1999a; Nichols, 2004). Cortical 5-HT<sub>2A</sub> receptors have been a natural focus to explain the psychotomimetic effects of lysergic acid diethylamide (LSD) or mescaline, since the cortex has one of the highest expressions of 5-HT<sub>2A</sub> receptor protein in the rodent and human brain. Secondly, one of the more popular models for studying hallucinogenic effects in rodents is the head shakes that are induced by all three major classes of serotonergic hallucinogens (phenethylamine, indoleamine and ergot hallucinogens). These head shakes can be induced by infusion of phenethylamine hallucinogens directly into the prelimbic region of the rat mPFC (Willins and Meltzer, 1997). An understanding of 5-HT<sub>2A</sub> receptor function in the prefrontal cortex is dependent upon understanding the electrophysiological actions of 5-HT<sub>2A</sub> receptors in all of the cellular compartments for which they are found. Cellular compartments where 5-HT<sub>2A</sub> receptors are localized to include post-synaptic sites on layer II, III, and V pyramidal cells, post-synaptic sites on certain GABAergic interneurons, glia, and a more controversial presence in axons projecting to layer V pyramidal cells.

In the prefrontal cortex, 5-HT<sub>2A</sub> receptors are known to have excitatory actions in many pyramidal cells, especially those in layer V, which are the principal cortical output cells (Araneda and Andrade, 1991; Amargos-Bosch *et al.*, 2004). In layer V pyramidal cells, direct activation of 5-HT<sub>2A</sub> receptor and 5-HT<sub>1A</sub> receptors mediates excitatory inward currents/depolarizing potentials and inhibitory outward currents/hyperpolarizing potentials (Figure 1), respectively (Araneda and Andrade, 1991; Tanaka and North, 1993). In fact, a majority of the electrophysiological effects of 5-HT upon pyramidal cells in the PFC and neocortex are direct inhibitory effects mediated by non-5-HT<sub>2A</sub> (effects such as suppressing electrically-evoked EPSPs) receptors, while the 5-HT<sub>2A</sub> receptor provides the major direct excitatory drive onto different cellular compartments such as glutamatergic pyramidal cells and GABAergic interneurons (Tanaka and North, 1993; Read *et al.*, 1994; Aghajanian and Marek, 1999b; Zhou and Hablitz, 1999).

**Figure 1** Opposing effects of postsynaptic excitatory 5-HT receptors and postsynaptic inhibitory 5-HT<sub>1A</sub> receptors on pyramidal cells in the medial prefrontal cortex/neocortex and the hippocampus. The 5-HT<sub>2A</sub> receptor and the 5-HT<sub>4</sub> receptor play similar roles with respect to physiological effects on pyramidal cells of the prefrontal cortex (PFC)/neocortex and the hippocampus, respectively, with respect to the reduction of the slow afterhyperpolarization (sAHP) and a slow depolarization. In both types of cortical regions, activation of 5-HT<sub>1A</sub> receptor exerts a slow hyperpolarization which acts in an opposite direction from the influence of 5-HT<sub>2A</sub> or 5-HT<sub>4</sub> receptor activation. This arrangement is highlighted here as the layer V pyramidal cells of the PFC/neocortex are the output cells of the allocortex and reflect integration of activity within cortical columns. Thus, antagonism of key 5-HT receptors at critical sites within microcircuits/macrocircuits could augment or attenuate the effects of therapeutic treatments such as serotonin reuptake inhibitors, which enhance activity at all 5-HT receptors.

### 5-HT<sub>2A</sub> receptors: excitation of cortical interneurons

5-HT<sub>2A</sub> receptors are known to be localized in both large and small GABAergic interneurons, including both parvalbumin- and calbindin-containing interneurons in the PFC and neocortex (Willins *et al.*, 1997; Jakab and Goldman-Rakic, 1998, 2000). In layer III pyramidal cells of the mPFC the influence of IPSCs from GABAergic interneurons via 5-HT<sub>2A</sub> receptor activation appears to be greater than in layer V pyramidal cells, where only about ~15 percent of the synaptic currents are IPSPs/IPSCs (Aghajanian and Marek, 1997; Zhou and Hablitz, 1999). In the hippocampus, the 5-HT<sub>2A</sub> and 5-HT<sub>3</sub> receptors appear to act together to excite GABAergic interneurons that induce IPSPs in the dentate gyrus and the CA1 pyramidal cells, respectively (Araneda and Andrade, 1991; Piguet and Galvan, 1994; Tanaka and North, 1993; Shen and Andrade, 1998). In the piriform cortex, a subpopulation of GABAergic cells are excited to fire action potentials in slices by 5-HT acting at 5-HT<sub>2A</sub> receptors (Sheldon and Aghajanian, 1990, 1991; Gellman and Aghajanian, 1994; Marek and Aghajanian, 1994). In these

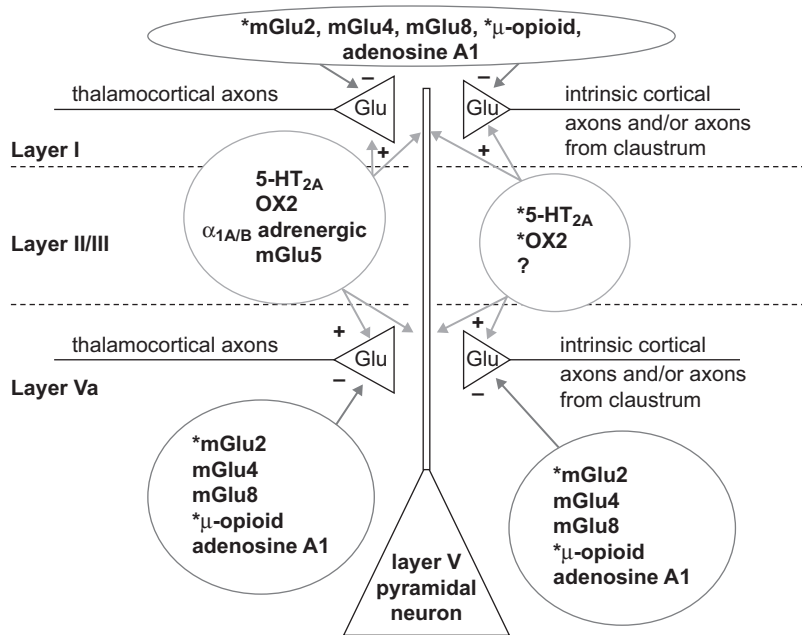

cells, both the indoleamine hallucinogen LSD and the phenethylamine hallucinogen DOI act as 5-HT<sub>2A</sub> receptor partial agonists (Marek and Aghajanian, 1996).

### 5-HT<sub>2A</sub> receptors enhance mPFC glutamate release

An electrophysiological action of 5-HT<sub>2A</sub> receptor activation first explicitly described in the mid-1990s may be especially relevant to understanding the important role this receptor plays in mediating the modulating or mediating salient effects of antidepressant, antipsychotic and hallucinogenic drugs. 5-HT<sub>2A</sub> receptor activation has been found to increase the frequency of spontaneous (not electrically-evoked) excitatory postsynaptic currents/potentials (EPSCs/EPSPs) when recording during slice preparations from the primary output cell of the PFC, the layer V pyramidal cells (Aghajanian and Marek, 1997). A survey of different cortical layers found that the frequency of excitatory synaptic currents induced in layer V pyramidal cells was at least four-fold greater than in layer II/III pyramidal cells. In contrast to layer V pyramidal cells, the layer VI pyramidal cells demonstrated no significant change in either the frequency or amplitude of EPSCs following 5-HT bath application (Lambe *et al.*, 2000). These excitatory synaptic currents induced by 5-HT<sub>2A</sub> receptor action are blocked by AMPA receptor activation in a manner consistent with a postsynaptic effect (Aghajanian and Marek, 1997; Zhang and Marek, 2008). In keeping with the hypothesis that these 5-HT-induced excitatory synaptic currents are linked to wider behavioral effects such as DOI-induced head shakes, AMPA receptor antagonists suppress DOI-induced head shakes (Zhang and Marek, 2008).

Several pharmacological aspects of suppressing these 5-HT-induced EPSCs suggest that a presynaptic mechanism may be involved. First, activation and blockade of mGlu2/3 receptors suppresses or enhances the frequency of 5-HT-induced EPSCs relative to changes in the amplitude of EPSCs consistent with a presynaptic influence of mGlu2 receptors on excitatory amino acid release (Marek *et al.*, 2000). Activation of mGlu2 receptors and blockade of mGlu2 receptors suppresses or enhances, respectively, the frequency of head shakes induced by phenethylamine hallucinogens (Benvenha *et al.*, 2006; Benneyworth *et al.*, 2007). This is of interest, not only from an antipsychotic drug development standpoint (Marek and Aghajanian, 1995; Patil *et al.*, 2007; Rorick-Kehn *et al.*, 2007a, 2007b), but is also intriguing given the primary physiological function of mGlu2 receptors as presynaptic autoreceptors present in the preterminal axonal compartments (Schoepp, 2001).

Other heteroreceptors interacting with 5-HT<sub>2A</sub> receptors both at the level of 5-HT-induced EPSCs in the mPFC

**Figure 2** 5-HT<sub>2A</sub> receptors work in tandem with other monoaminergic ( $\alpha_{1A/B}$ -adrenergic), glutamatergic (mGlu5), and peptidergic (orexin OX2) receptors to enhance glutamate release (spontaneous excitatory postsynaptic potentials (EPSPs)/excitatory postsynaptic currents (EPSCs)) onto the apical dendritic tree of layer V pyramidal cells (layers I and Va) from both thalamocortical and claustral/intrinsic cortical afferents. In the thalamocortical and claustral/intrinsic cortical afferents, metabotropic glutamate (mGlu2, mGlu4 and mGlu8) autoreceptors,  $\mu$ -opioid heteroreceptors, and adenosine A1 heteroreceptors act to attenuate glutamate release. Evidence supporting the existence of thalamocortical mGlu2 autoreceptors and thalamocortical  $\mu$ -opioid heteroreceptors also includes data from lesion studies (\*). These relationships emphasize the manner in which single 5-HT receptors may work in tandem with a variety of other aminergic, glutamatergic and peptidergic receptors. Challenges remain in understanding the nature of the relationship between modulation of synaptic inputs to layer V pyramidal cells versus postsynaptic modulation of the passive properties of these same layer V pyramidal cells shown in Figure 1. In addition, where both positive and negative presynaptic modulation of excitatory neurotransmission occurs, challenges also remain in addressing whether this modulations occurs in preterminal axons or in axon terminals or in both. An unresolved issue at the present time is whether the non-thalamic component of the 5-HT-induced EPSCs is mediated through afferents from intrinsic cortical neurons vs. afferents from a structure such as the claustrum.

and also with respect to DOI-induced head shakes are  $\mu$ -opioid receptors. Activation of  $\mu$ -opioid receptors, but not  $\kappa$ - or  $\delta$ -opioid receptors, suppresses 5-HT-induced EPSCs with little, if any, evidence for simultaneous postsynaptic effects in the layer V pyramidal cells (Marek and Aghajanian, 1998). Similarly, activation of  $\mu$ -opioid receptors, but not  $\kappa$ - or  $\delta$ -opioid receptors, suppresses DOI-induced head shakes (Marek, 2003). The importance of this interaction is the widespread physiological role played by inhibition of neurotransmitter release for all of the opioid receptors.

A third heteroreceptor interaction with 5-HT<sub>2A</sub> receptors both at the level of 5-HT-induced EPSCs in the mPFC and also with respect to DOI-induced head shakes is that of adenosine A1 receptors. Activation of adenosine A1 receptors selectively suppressed 5-HT-induced EPSCs recorded from layer V pyramidal cells, but did not suppress fast EPSCs evoked by stimulation of the white matter (Stutzman *et al.*, 2001). Activation and blockade

of adenosine A1 receptors also suppressed and enhanced, respectively, DOI-induced head shakes (Marek, 2009). Again, the importance of these observations is in the widely accepted physiological heteroreceptor role played by adenosine A1 receptors in glutamatergic neuron axons and the extensive overlap between mGlu2 and adenosine A1 receptors (Figure 2).

A presynaptic role for 5-HT<sub>2A</sub> receptors in mediating this increase in the frequency of EPSCs was not supported by the experiments with tetrodotoxin (TTX) and the subsequent block of impulse flow. Usually spontaneous neurotransmitter release induced by a presynaptic heteroreceptor is not suppressed by TTX administration. However, the 5-HT-induced EPSCs are totally suppressed by application of TTX onto the slice (Aghajanian and Marek, 1997). Since mGlu2 receptors generally are not in the presynaptic terminal and are often located in a preterminal region of the axon, it would also seem consistent that 5-HT<sub>2A</sub> receptors inducing glutamate release might be proximal

in the axonal arbor to the mGlu2 receptors. In fact, some axonal arbors such as thalamocortical axons are known to support local or ectopic impulse flow (Pinault, 1995). Experiments utilizing transgenic strategies such as deletion of 5-HT<sub>2A</sub> receptors and then local rescue of 5-HT<sub>2A</sub> receptors in the cortex have suggested that the source of glutamate being released by 5-HT<sub>2A</sub> receptor activation is on afferents to layer V pyramidal cells rather than retrograde release phenomena such as occur with cannabinoids and arachidonic acid (Beique *et al.*, 2007).

### *Thalamocortical pathways and 5-HT<sub>2A</sub> receptors*

Lesion studies directed at determining the source of a subcortical glutamatergic afferent have suggested that the thalamus contributes to a substantial portion (50–60 percent) of the 5-HT-induced EPSCs. Both fiber-sparing NMDA-induced lesions and electrolytic lesions reduced the frequency of 5-HT-induced EPSCs by ~50–60 percent (Lambe and Aghajanian, 2001; Marek *et al.*, 2001). The importance of this finding is the excellent match between the layers of the PFC and neocortex where 5-HT<sub>2A</sub> receptors are most densely expressed (layers I and Va) and the layers where local application of 5-HT from a glass micropipette induces the excitatory current within seconds despite the absence of cells in these layers which fire in response to 5-HT (Aghajanian and Marek, 1997). Furthermore, the intralaminar and midline thalamic nuclei terminate most heavily in layers I and Va, which are the layers where 5-HT-induced EPSCs are supported by local application. Accordingly, three GPCRs (mGlu2 autoreceptors,  $\mu$ -opioid heteroreceptors and adenosine A1 receptors) whose activation suppresses 5-HT-induced EPSCs have mRNA expressed in the midline and thalamic intralaminar nuclei. These three presynaptic or preterminal receptors are expressed in a laminar pattern in the cortex (heaviest in layers I and Va) consistent with autoreceptor and heteroreceptor function, respectively, from these thalamic nuclei intimately involved in arousal and attention. Furthermore, the binding of agonist radiotracers for mGlu2 and  $\mu$ -opioid receptors were decreased by the same thalamic lesions which suppressed by ~50–60 percent, but did not completely eliminate, the 5-HT-induced EPSCs (Marek *et al.*, 2001).

Other observations besides the regulation of DOI-induced head shakes support functional relationships in thalamocortical pathways. For example, the DOI-induced increase in c-fos expression in the somatosensory cortex is attenuated by lesions which destroy the posterior thalamic nucleus and VPM/VPL (Scruggs *et al.*, 2000). Thus, the intralaminar and midline thalamic nuclei may be one of several sources of afferents upon which 5-HT<sub>2A</sub> receptor

activation induces glutamate release into the apical dendrites (layers I and Va) of the layer V pyramidal cells.

### *Challenges to presynaptic thalamocortical 5-HT<sub>2A</sub> receptors*

A series of studies employing mice with a deletion of 5-HT<sub>2A</sub> receptors and then rescue strategies to recover 5-HT<sub>2A</sub> receptors either in the prefrontal cortex/neocortex and the thalamus has challenged the hypothesis that 5-HT<sub>2A</sub> receptors are acting in a presynaptic manner. These studies have demonstrated a loss of 5-HT-induced EPSCs, DOI-induced immediate early gene expression, and DOI-induced head shakes in transgenic mice lacking 5-HT<sub>2A</sub> receptors (Weisstaub *et al.*, 2006; Gonzalez-Maeso *et al.*, 2007). These electrophysiological, biochemical and behavioral effects have been rescued in transgenic mice with a rescue of cortical 5-HT<sub>2A</sub> receptors, but not in mice with a rescue of thalamic 5-HT<sub>2A</sub> receptors. However, both of these genetic rescue strategies are compromised by serious confounds. The use of the gene *Emx1* to drive cortical 5-HT<sub>2A</sub> expression in the *htr2a*<sup>-/-</sup> mice also led to expression of 5-HT<sub>2A</sub> receptors in the claustrum. The claustrum is an additional candidate area, besides the midline and intralaminar thalamic nuclei, which also sends cortical projections to layers I and V of the prefrontal cortex and neocortex, and is activated by 5-HT<sub>2A</sub> receptor expression as judged by immediate early gene expression. While not well understood, and infrequently studied, the claustrum is known to be involved in the multi-modal sensory processing throughout the cortex. Thus, afferents from the association cortex or neocortex form only one of two known candidate regions (the other being the claustrum) where 5-HT<sub>2A</sub> receptors are rescued in the *htr2a*<sup>-/-</sup> x *Emx1-Cre* mice.

Confounds also compromise the use of a rescue strategy for putative thalamic 5-HT<sub>2A</sub> receptors. The thalamic rescue strategy introduced the 5-HT<sub>2A</sub> receptor gene into a region controlled by a promoter for the transient expression of the serotonin transporter in all of the ‘first-order’ or sensory thalamic nuclei, such as the dorsal lateral geniculate, medial geniculate nucleus, ventroposterior medial and ventroposterior lateral nuclei, and the ventral lateral and ventral anterior nuclei (Lebrand *et al.*, 1996; Persico *et al.*, 2001). These first-order nuclei project primarily to the mid-layer of the cortex or layer IV, and tend to receive cortical afferents (modulatory inputs) from layer VI pyramidal cells rather than layer V pyramidal cells. These first-order thalamic nuclei do not send a significant projection to layer I of the prefrontal cortex and neocortex, as is the case for the midline and intralaminar thalamic nuclei. The midline and intralaminar thalamic

neurons also receive 'driver' inputs from layer V pyramidal cells (Sherman and Guillery, 1996, 1998). Given the lack of available evidence that the midline and intralaminar thalamic nuclei possess transient expression of the serotonin transporter, as do the first-order thalamic nuclei, the use of *ht2r*<sup>-/-</sup> × *Htt-Cre* mice might have limited 5-HT<sub>2A</sub> receptor expression to thalamic neurons (e.g., sensory thalamic nuclei) which are not the candidate thalamic nuclei hypothesized to mediate 50–60 percent of the 5-HT-induced EPSCs in rats. It should be pointed out, however, that other evidence from *in vivo* electrophysiological experiments with anesthetized rats and *in vivo* dialysis has not supported the hypothesis that 5-HT<sub>2A</sub> receptors induce local cortical effects via releasing glutamate from thalamocortical neurons (Puig *et al.*, 2003). Understanding the importance of 5-HT<sub>2A</sub> receptor activation in modulating afferent axons to the layer V pyramidal cells as opposed to the simple postsynaptic effects of 5-HT<sub>2A</sub> receptors will require further correlation to higher-order behavioral functions, such as different executive functions of the PFC.

### **5-HT<sub>2A</sub> receptors: antidepressant-mediated down-regulation**

A substantial body of literature has grown describing the down-regulation/desensitization of 5-HT<sub>2A</sub> receptor binding/functional 5-HT<sub>2A</sub> receptor mediated responses in the mPFC following the chronic administration of most antidepressants other than SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs). There has been relatively little study of the modulation of 5-HT<sub>2A</sub> receptor-mediated responses at the single-cell level. A subchronic duration of imipramine treatment (15mg/kg × 21 days) has been found to down-regulate the maximal response observed both for 5-HT-induced EPSCs and the 5-HT-induced excitation of piriform cortical interneurons (Marek, 2008a). These results agree with a plethora of studies showing down-regulation of 5-HT<sub>2A</sub> receptor binding by imipramine and other TCAs. A dissociation was observed for the effects of 10 daily electroconvulsive treatments on cortical 5-HT<sub>2A</sub> receptors. This subchronic electroconvulsive shock (ECS) treatment desensitized the 5-HT-induced EPSCs while increasing the maximal response of cortical GABAergic interneurons to 5-HT (Marek, 2008a). Thus, both subchronic imipramine and ECS treatment down-regulated/desensitized glutamatergic compartments to the effects of 5-HT<sub>2A</sub> receptor activation. In contrast, the concentration–response curve for 5-HT-induced EPSCs was similar in PFC slices from both subchronic fluoxetine (10mg/kg × 21 days) and vehicle-treated rats (Marek, 2008b). In extracellular recordings examining the effects

of 5-HT receptor agonists on spontaneous epileptiform discharges induced in an Mg<sup>2+</sup>-free slice perfused with picrotoxin, the ability of 8-OH-DPAT to suppress epileptiform activity was enhanced while the ability of DOI to enhance these discharges was attenuated (Bobula *et al.*, 2003). These findings are in general agreement with the opposing action of cortical 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors, and that the balance of activity with chronic antidepressant treatment is toward inhibitory actions of 5-HT and away from the excitatory actions of 5-HT<sub>2A</sub> receptor activation.

Other important roles exist for 5-HT<sub>2A</sub> receptors such as the modulation of locus coeruleus activity (Rasmussen and Aghajanian, 1986, 1988). The 5-HT<sub>2A</sub> receptor appears to specifically regulate dopaminergic VTA neurons (see work by E. Pehek and B. Roth); this relationship is relevant to the involvement of these pathways in responses to environmental stress.

### **5-HT<sub>2B</sub> receptors**

5-HT<sub>2B</sub> mRNA has been detected at low levels in the brain of cat and monkey, but not rat (Helton *et al.*, 1994; Schmuck *et al.*, 1994). This receptor is present in highest abundance in the liver and kidney. Agonist action at this receptor has also been suggested to be the mechanism underlying the valvular heart disease associated with fenfluramine (Evrard *et al.*, 1999; Rothman *et al.*, 2000), precluding significant interest by the pharmaceutical industry in this target with limited brain distribution.

### **5-HT<sub>2C</sub> receptors**

Unlike 5-HT<sub>2A</sub> receptors, which are preferentially distributed to the prefrontal cortex and neocortex, 5-HT<sub>2C</sub> receptors are preferentially distributed to subcortical regions, including the basal ganglia and related structures (Mengod *et al.*, 1990; Wright *et al.*, 1995; Lopez-Gimenez *et al.*, 1997, 1998, 2001). 5-HT<sub>2C</sub> receptors play a role in mediating effects in a number of basal ganglia-related structures ranging from the substantia nigra pars reticulata (SNpr), substantia nigra pars compacta (SNpc), ventral tegmental area (VTA), striatum and globus pallidus to the subthalamic nucleus. 5-HT<sub>2C</sub> receptor activation induced inward currents in SNpr neurons in addition to increasing the frequency of GABA<sub>A</sub> receptor-mediated IPSCs, which were probably due to excitation of other GABAergic SNpr neurons (Stanford and Lacey, 1996). The 5-HT<sub>2C/1B</sub> receptor agonist m-chlorophenylpiperazine (mCPP) excited all non-dopaminergic neurons in the VTA while differentially increasing the firing rate of

non-dopaminergic SNpr cells depending on whether these cells also responded to a peripheral footpinch stimulus (Di Giovanni *et al.*, 2001). A number of 5-HT<sub>2C</sub> receptor agonists (RO 60-0175, mCPP, MK-801) increased the firing frequency of dopaminergic VTA cells, often with an increase in burst frequency or spike frequency within bursts that typically result in supralinear dopamine release in terminal fields (Di Matteo *et al.*, 1999, 2000, 2001; Di Giovanni *et al.*, 2000, 2001; Gobert *et al.*, 2000). A number of 5-HT<sub>2C</sub> receptor antagonists either blocked the effects of the 5-HT<sub>2C</sub> agonist or decreased the firing rate of VTA cells. In contrast to the VTA cells, 5-HT<sub>2C</sub> receptor agonists and antagonists had little, if any, effect on dopaminergic SNpc neurons (Di Matteo *et al.*, 1999; Di Giovanni *et al.*, 2000). Another differential effect of 5-HT<sub>2A/2C</sub> receptor agonism was seen in the interaction with a dopamine D2 receptor-mediated inhibition of the firing rate. Both a selective 5-HT<sub>2A</sub> receptor antagonist and a selective 5-HT<sub>2C</sub> receptor antagonist blocked the DOI-induced enhancement of the quinpirole (D2 receptor agonist)-induced reduction of VTA cells. DOI did not enhance the quinpirole-induced reduction in the firing rate of SNpc (A9) cells (Olijslagers *et al.*, 2004).

5-HT<sub>2C</sub> receptors exert direct excitatory effects on neurons from regions of the basal ganglia outside of the brainstem VTA and the substantia nigra. Striatal cholinergic interneurons contain 5-HT<sub>2C</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptor mRNA. Depolarization or inward currents can be induced by 5-HT, and is mediated by all three of these 5-HT receptor subtypes (Bonsi *et al.*, 2007). In the subthalamic nucleus, 5-HT<sub>2C</sub> and 5-HT<sub>4</sub> receptor activation induces direct postsynaptic excitatory effects while activation of the 5-HT<sub>1A</sub> receptor mediates a postsynaptic inhibitory effect (Stanford *et al.*, 2005). Thus, 5-HT<sub>2C</sub> receptors are densely expressed in the basal ganglia-related structures and exert direct excitatory effects in a variety of neuron types throughout this motor circuitry. Given the preclinical antipsychotic-like profile exerted by 5-HT<sub>2C</sub> receptor agonists, the results of phase II clinical testing for the Wyeth 5-HT<sub>2C</sub> receptor agonist vabicaserin in schizophrenia patients should be informative.

### 5-HT<sub>3</sub> receptors

The 5-HT<sub>3</sub> receptors form the only 5-HT receptor subtype which functions as a ligand-gated ion channel (i.e., an ionotropic receptor). This receptor was, in the original classification of 5-HT receptors by Gaddum and Picarelli, known as the M-receptor. Two different subunits, 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub>, are present in peripheral sites, whereas only the 5-HT<sub>3A</sub> receptor subunit is present in central neurons (Morales and Wang, 2002). While a high density of

5-HT<sub>3</sub> receptors is found in the hindbrain in areas thought to play a role in anti-emetic uses of 5-HT<sub>3</sub> antagonists (e.g., ondansetron and metoclopramide), a moderate density of 5-HT<sub>3</sub> receptors is present in the prefrontal cortex, neocortex, hippocampus and amygdala. In these forebrain regions, 5-HT<sub>3</sub> receptors are localized in many of the calbindin- and CCK-containing interneurons (Morales and Bloom, 1997). 5-HT<sub>3</sub> receptors also are localized to some calretinin-containing interneurons, especially in the agranular insular cortex and the piriform cortex.

### Hippocampal 5-HT<sub>3</sub> receptors in interneurons

Initial experiments with central neurons found that 5-HT or 2-methyl-5-HT are agonists that induce rapidly desensitizing responses; the excitatory responses in cultured hippocampal neurons were blocked by ICS-205-930, curare or metoclopramide (Yakel and Jackson, 1988). Recordings from the dentate gyrus of hippocampal slices revealed that both GABAergic basket cells and the principal excitatory cell dentate cells responded to 5-HT with spontaneous IPSCs which were blocked by the GABA<sub>A</sub> receptor antagonist bicuculline (Kawa, 1994). In addition to this apparent excitatory action of 5-HT<sub>3</sub> receptors on GABA release, activation of 5-HT<sub>3</sub> receptors also induced inward currents in the basket cells. Hippocampal GABAergic interneurons located in the stratum radiatum of the CA1 field, which receives a strong projection from the median raphe nuclei, are directly excited by postsynaptic 5-HT<sub>3</sub> receptors (McMahon and Kauer, 1997). These interneurons in CA1 send axonal projections to the dentate gyrus, as well as extensive ramifications within CA1. Another study using single-cell RT-PCR found that only the short splice variant of the 5-HT<sub>3A</sub> receptor subunit was expressed in hippocampal interneurons of CA1 (Sudweeks *et al.*, 2002). Furthermore, half the interneurons containing 5-HT<sub>3</sub> receptors appeared to assemble with  $\alpha 4\beta 2$  nicotine receptor subunits to form functional heteromeric receptors. More recent work using single rat hippocampal neuron cultures has confirmed that 5-HT<sub>3</sub> receptors control GABA, but not glutamate, release (Dorostkar and Boehm, 2007). Further, activation of 5-HT<sub>3</sub> receptors mediates opposite effects on spontaneous as compared to action-dependent release. Finally, the presynaptic action of 5-HT<sub>3</sub> receptor activation to enhance GABA release onto CA3 pyramidal cells was found to gradually increase with development (Choi *et al.*, 2007).

Multiple 5-HT receptors may act together or oppose each other in different hippocampal cellular compartments. For example, in the dentate gyrus granule cells, a postsynaptic effect of 5-HT<sub>1A</sub> receptor activation leads to hyperpolarization (Piguet and Galvan, 1994). In contrast,

very brief local 5-HT applications induce a hyperpolarization and a transient burst of spontaneous IPSPs that are blocked by tetrodotoxin or 5-HT<sub>3</sub> receptor antagonists (Piguet and Galvan, 1994). More prolonged increases in spontaneous IPSPs induced by 5-HT were blocked by the 5-HT<sub>2A</sub> receptor antagonist M100907 (Piguet and Galvan, 1994). Using a 'synaptic bouton preparation' by acutely isolating CA1 neurons allowed for studying the presence of multiple 5-HT receptors in GABAergic nerve terminals (Katsurabayashi *et al.*, 2003). The GABAergic interneuron terminals within the CA1 hippocampal field have also been shown to contain 5-HT<sub>1A</sub> heteroreceptors. All of the terminals were found to contain 5-HT<sub>1A</sub> receptors, while only a subset contained both inhibitory 5-HT<sub>1A</sub> receptors and excitatory 5-HT<sub>3</sub> receptors (Katsurabayashi *et al.*, 2003). Accordingly, a 5-HT<sub>1A</sub> receptor antagonist WAY100635 and a 5-HT<sub>3</sub> receptor antagonist Y-25130 had opposing influences on hippocampal high-frequency (200-Hz) or 'ripple' oscillations in the CA1 area of awake, behaving rats (Ponomarenko *et al.*, 2003).

### ***Amygdaloid 5-HT<sub>3</sub> receptors***

5-HT<sub>3</sub> receptors play a physiological role in both the lateral amygdala and the basolateral amygdala. In the lateral amygdala brain slices, 5-HT<sub>3</sub> receptor activation was found to increase excitatory synaptic potentials (Sugita *et al.*, 1992). In contrast, recordings made from mechanically dissociated BLA neurons with preserved presynaptic nerve terminals found that 5-HT<sub>3</sub> receptor activation had only a presynaptic effect to increase GABA release from the terminals of interneurons (Koyama *et al.*, 2000). Somewhat analogous to the interactions of 5-HT<sub>3</sub> and 5-HT<sub>1A</sub> receptors in GABAergic terminals in the CA1 hippocampus, activation of heteroreceptors for both of these 5-HT receptors on GABAergic nerve terminals of the BLA had opposing effects on the frequency of miniature IPSCs (Koyama *et al.*, 2002b).

### ***Prefrontal cortical/neocortical 5-HT<sub>3</sub> receptors***

An important role for 5-HT<sub>3</sub> receptors in the prefrontal cortex and neocortex has been identified based on the observation that over 90 percent of the cortical and hippocampal neurons expressing 5-HT<sub>3</sub> receptors are GABAergic interneurons (Morales *et al.*, 1996). With respect to calcium binding proteins, the 5-HT<sub>3</sub> receptors are not found in parvalbumin-containing interneurons, but are expressed in either calbindin- or calretinin-containing interneurons (Morales and Bloom, 1997). With respect to

peptides, the 5-HT<sub>3</sub> receptors are present in 35–66 percent of CCK-containing interneurons in different cortical regions (Morales and Bloom, 1997). However, 5-HT<sub>3</sub> receptors are not co-localized in somatostatin-expressing interneurons. An important role for 5-HT<sub>3</sub> receptors expressed in cortical interneurons is also present for primates. 5-HT<sub>3</sub> receptors are present in interneurons targeting pyramidal cells dendrites, small GABA-, substance P receptor-, and calbindin-containing interneurons, and medium-size calretinin-containing interneurons in the macaque cerebral cortex (Jakab and Goldman-Rakic, 2000). Electrophysiological studies have found that 5-HT<sub>3</sub> receptor activation can suppress spontaneously active cells in the rat mPFC (Ashby *et al.*, 1989). The suggestion that this is a direct effect, though, appears to be in contradiction to the overwhelming expression of 5-HT<sub>3</sub> receptors in interneurons. A large, desensitizing inward current and a transient enhancement of spontaneous IPSCs can also be seen in a minority of interneurons in the rat PFC (Zhou and Hablitz, 1999). However, 5-HT<sub>2A</sub> receptor-mediated changes in spontaneous IPSCs were much more frequent than 5-HT<sub>3</sub> receptor effects. Intracellular recordings from fast-spiking (FS) interneurons, low threshold spike (LTS) interneurons, and pyramidal cells of the visual cortex revealed opposing effects of 5-HT<sub>3</sub> and 5-HT<sub>1A</sub> receptors somewhat analogous to findings in the hippocampus and amygdala (Xiang and Prince, 2003). Approximately 75 percent of the FS and LTS interneurons responded to 5-HT. 5-HT induced outward currents in 50 percent of 5-HT-responsive FS interneurons; these inward currents were blocked by a 5-HT<sub>3</sub> receptor antagonist tropisetron. 5-HT induced outward currents in 41 percent of the responsive cells' FS interneurons; these outward currents were blocked by the 5-HT<sub>1A</sub> receptor antagonist NAN-190. Outward currents blocked by NAN-190 were preferentially induced in LTS cells (81 percent of 5-HT-responsive cells). In contrast, 5-HT-induced inward currents (blocked by tropisetron) in only 15 percent of 5-HT-responsive LTS cells.

### ***5-HT<sub>3</sub> receptors and dopamine-containing midbrain cells***

The ability of 5-HT<sub>3</sub> receptor antagonists to block dopamine-mediated effects, especially using local administration of dopamine agonists in the nucleus accumbens, prompted intense interest in the potential antipsychotic action for this class of compounds (Costall and Naylor, 1994). Differences in the ability of antipsychotic drugs to decrease the spontaneous activity of neurons in the ventral tegmental area (VTA; A10) compared to the substantia nigra pars compacta (SNpc; A9) has been proposed and

studied as a means to predict atypical antipsychotic action (Grace *et al.*, 1997). Emerging dopamine-cell depolarization block with continued administration of antipsychotic drugs has been suggested to mediate these effects. The emergence of the depolarization block can be empirically demonstrated by apomorphine reversing the chronic effects of the antipsychotic drug upon the firing rate of the dopamine-containing cells.

The effects of 5-HT<sub>3</sub> receptor antagonists in the dopamine-cell depolarization block paradigm have been inconsistent. For example, MDL 73,147EF (palonosetron), unlike haloperidol, did not acutely increase the number of active dopamine neurons in A9. However, when given subchronically, MDL 73,147EF (like haloperidol) decreased the number of active A10 (VTA) and A9 (SNpc) cells (Sorensen *et al.*, 1989). Chronic administration of another 5-HT<sub>3</sub> receptor antagonist, BRL 43694, failed to alter the number of active dopamine neurons encountered in either A10 (VTA) or A9 (SNpc) as seen with known antipsychotic drugs (Ashby *et al.*, 1990). The effects of another 5-HT<sub>3</sub> receptor antagonist were different from those of these other 5-HT<sub>3</sub> receptor antagonists and antipsychotic drugs. Acute and chronic administration of zatosetron (LY277359) decreased the number of spontaneously active A10 (VTA) cells without altering A9 (SNpc) cells (Rasmussen *et al.*, 1991). While chronic zatosetron did decrease the spontaneous firing rate of A10 cells similar to atypical antipsychotic drugs, this effect was not reversed by apomorphine as seen for atypical antipsychotic drug-induced depolarization block of dopamine-containing cells. However, the data from a double-blind, placebo-controlled trial of ondansetron in schizophrenic patients was generally negative (Costall and Naylor, 1994). The clinical evidence for anxiolytic activity with 5-HT<sub>3</sub> receptor antagonists is also far from compelling (Greenshaw and Silverstone, 1997). This raises a fundamental question as to whether this lack of translation from the preclinical arena to the clinic is because modulating only a few subpopulations of GABAergic interneuron is not enough for a robust therapeutic effect, or because the model systems used to increase enthusiasm in this target are limited compared to those used to drive the successful translation of mGlu2/3 receptor agonists (e.g., positive phase II or phase III data for schizophrenia and GAD). Alternatively, clinical studies with 5-HT<sub>3</sub> receptor antagonists were conducted in the absence of a radiotracer for receptor occupancy or other robust biomarker strategies so that the optimal dose may not have been tested.

An additional aspect of 5-HT<sub>3</sub> receptors not discussed here is their sensitivity to alcohol. The reader is referred to a number of manuscripts by David Lovinger and colleagues which discuss this functional relationship.

## 5-HT<sub>4</sub> receptors

An extensive number of studies have looked at depolarizing effects of 5-HT in the hippocampus that are mediated by activation of 5-HT<sub>4</sub> receptors. In addition to hyperpolarizing effects of 5-HT<sub>1A</sub> receptor activation, 5-HT exerts several other prominent postsynaptic effects on hippocampal CA1 pyramidal neurons, including a slow membrane depolarization and a reduction of the after-hyperpolarization potential or AHP (Andrade and Nicoll, 1987; Colino and Halliwell, 1987; Chaput *et al.*, 1990). Further pharmacological experiments characterized these responses as due to 5-HT<sub>4</sub> receptor activation (Andrade and Chaput, 1991b; Beck, 1992; Torres *et al.*, 1994; Birnstiel and Beck, 1995). In fact, Andrade and Chaput noted that a number of the cellular effects mediated by activation of 5-HT<sub>2A</sub> receptors in the prefrontal cortex and neocortex are mediated by 5-HT<sub>4</sub> receptor activation (see Figure 1) in the hippocampus (Andrade and Chaput, 1991b).

5-HT<sub>4</sub> receptor activation, via a presynaptic action, has also been found to potentiate the synapse from mossy fibers (originating from dentate granule cells) terminating onto CA3 pyramidal cells (Kobayashi *et al.*, 2008) in several different strains of mice. 5-HT<sub>1A</sub> receptor action depressed this same synapse. Interestingly, chronic fluoxetine (10 mg/kg per day) enhanced the 5-HT<sub>4</sub> receptor-mediated potentiation of the mossy fiber-CA3 synapse at low 5-HT concentrations, and attenuated the 5-HT-induced potentiation at high 5-HT concentrations. Chronic oral fluoxetine treatment did not alter light/dark behavior, elevated plus maze behavior, and immobility in the forced swim test. This treatment did, however, reduce the activity of these mice in a novel environment.

As discussed previously, activation of 5-HT<sub>4</sub> receptors exerts depolarizing effects in several movement-related regions with the 5-HT<sub>2C</sub> receptor. These regions include the subthalamic nucleus (Stanford *et al.*, 2005; Xiang *et al.*, 2005) and the globus pallidus (Shen *et al.*, 2007; Chen *et al.*, 2008).

5-HT<sub>4</sub> receptor stimulation has been found to potentiate the dendritic population EPSP evoked in the stratum radiatum of the CA1 hippocampal field by stimulation of the Schaffer collateral pathway (Tokarski and Bijak, 1996; Bijak, 1997; Matsumoto *et al.*, 2001). Chronic administration of antidepressants (the TCA imipramine and three SSRIs) was found to attenuate effects of 5-HT<sub>4</sub> receptor-induced potentiation of the Schaffer collateral stimulation (Tokarski and Bijak, 1996; Bijak, 1997). Given that 5-HT<sub>1A</sub> receptor-mediated inhibitory responses tend to be enhanced, antidepressant-induced regulation of 5-HT responses in the hippocampal formation appears to shift the balance of activity towards inhibitory effects and away from the 5-HT<sub>4</sub> receptor-mediated excitatory effects.

## 5-HT<sub>5</sub> receptors

The 5-HT<sub>5A</sub> (expressed in human, rat and mouse) and 5-HT<sub>5B</sub> (expressed in rat and mouse, but not human) receptors were recently reviewed (Nelson, 2004). This receptor also has been plagued by a relative lack of specific reagents. However, the localization of 5-HT<sub>5A</sub> receptor mRNA in the mouse or rat cerebral cortex, hippocampal CA1-3 fields, and habenula is quite intriguing. The 5-HT<sub>5A</sub> receptor mRNA in the habenula coupled with immunohistochemical evidence of 5-HT<sub>5A</sub> receptor expression on dorsal raphe serotonergic cell bodies and axons raises interesting functional questions. What is the nature of serotonergic modulation of long-loop feedback from forebrain regions (excluding the prefrontal cortex) to the raphe nuclei? Do 5-HT<sub>5A</sub> receptors play an autoreceptor function in the raphe nuclei themselves?

## 5-HT<sub>6</sub> receptors

A 5-HT<sub>6</sub> receptor antibody showed the highest immunoreactivity in the plexiform layer of the olfactory tubercle, the frontal cortex and entorhinal cortex, nucleus accumbens, striatum, hippocampus (stratum oriens and radiatum of the CA1 field, molecular layer of dentate gyrus), and the molecular layer of the cerebellum. A moderate intensity of specific immunolabeling was seen in the thalamus, substantia nigra, superficial layer of the superior colliculus, motor trigeminal and facial nucleus. The distribution of immunoreactivity for the 5-HT<sub>6</sub> receptor was similar to the 5-HT<sub>6</sub> receptor mRNA distribution (Gerard *et al.*, 1996, 1997). Frankly, much of the interest in this receptor as a target for cognition impairment associated with schizophrenia (CIAS) has been driven by the relatively high affinity of clozapine and olanzapine for the 5-HT<sub>6</sub> receptor. These data have been complemented by the effects of 5-HT<sub>6</sub> receptor antagonists in increasing extracellular levels of acetylcholine and glutamate in the forebrain, in addition to improving cognition in rodents.

5-HT<sub>6</sub> receptor antagonists generally do not have effects in behavioral or electrophysiological screens for antipsychotic drugs. The repeated oral administration of the 5-HT<sub>6</sub> receptor antagonist SB-271046 (1–10 mg/kg  $\times$  21 days) did not alter the firing pattern of dopaminergic neurons in the VTA compared to vehicle-treated animals. The two higher doses did increase the number of spontaneously active SNC dopaminergic neurons compared to control (Gerard *et al.*, 1996, 1997; Minabe *et al.*, 2004). This finding would not necessarily contradict the hypothesis that 5-HT<sub>6</sub> receptors might be targets for treating the cognitive impairment associated with schizophrenia (CIAS). However, despite a press release in December 2005

citing positive effects of the 5-HT<sub>6</sub> receptor antagonist SGS518 or LY483518 for the treatment of CIAS, there are no studies for this putative medication currently in progress cited at the clinical trial registry ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)).

There is relatively little in the way of other electrophysiological studies addressing 5-HT<sub>6</sub> receptors. In addition to a positive role for 5-HT<sub>2C</sub> and 5-HT<sub>7</sub> receptors, activation of 5-HT<sub>6</sub> receptors appears to depolarize and induce inward currents in cholinergic interneurons of the striatum (Bonsi *et al.*, 2007). While optimal agonist reagents are not available, a number of antagonist reagents are available, which can be synthesized and used in experiments to better understand the physiological role played by this 5-HT receptor.

## 5-HT<sub>7</sub> receptors

Amongst the regions with the highest concentration of 5-HT<sub>7</sub> receptors in the human brain, by [<sup>3</sup>H]SB-269970 autoradiography, are the anterior thalamus, mediodorsal thalamus, dentate gyrus, pulvinar, substantia nigra, VTA, dorsal raphe nuclei, hippocampus, hypothalamus and anterior cingulate cortex (Varnas *et al.*, 2004). The 5-HT<sub>7</sub> receptor is known to be coupled to G<sub>s</sub> proteins, leading to an increase in cAMP concentration that frequently results in a direct depolarizing or excitatory effect.

### Hippocampal 5-HT<sub>7</sub> receptors

One of the initial pharmacological characterizations of a 5-HT<sub>7</sub> receptor-mediated electrophysiological response in the forebrain was in the hippocampus (Bacon and Beck, 2000). Activation of 5-HT<sub>7</sub> receptors increased the excitability of CA3 pyramidal cells in brain slice experiments as 5-HT was found to decrease the slow afterhyperpolarization (sAHP) in a concentration-dependent manner. The rank order of potency of other 5-HT agonists (5-carboxyamidotryptamine [5-CT] > 5-HT > 5-methoxytryptamine (5-MeOT) to decrease sAHP agreed well with their affinity for the 5-HT<sub>7</sub> receptor during experiments where WAY-100635 and GR-113808 were used to block 5-HT<sub>1A</sub> and 5-HT<sub>4</sub> receptors, respectively. Furthermore, the 5-HT<sub>2A/2C</sub>, 5-HT<sub>3</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>1D</sub> and 5-HT<sub>6</sub> receptors were ruled out as agonists for this electrophysiological response, as agonists for these 5-HT receptors (DOI, 2-methyl 5-HT,  $\alpha$ -methyl 5-HT, sumatriptan and clozapine) did not mimic the effect of 5-HT at 10- $\mu$ M concentrations. Formal analysis of 5-HT receptor antagonists with Schild analyses using the relatively selective 5-HT<sub>7</sub>

receptor antagonist SB-269770, mesulergine and ritanserin was also consistent with the involvement of the 5-HT<sub>7</sub> receptor in this response. In contrast, antagonists for the 5-HT<sub>2A/2C</sub>, 5-HT<sub>6</sub> receptors (clozapine) and 5-HT<sub>3</sub> receptors (ICS-205,930) had no effect on the 5-HT-induced decrease in sAHP. Interestingly, clozapine had little effect either as an agonist or an antagonist for the 5-HT-induced suppression of the sAHP in hippocampal CA3 pyramidal cells. A 5-HT-induced decrease in sAHP and frequency adaptation of action potential firing that is mediated via 5-HT<sub>7</sub> receptor activation has also been found when recording from pyramidal cells of the CA1 area during rat hippocampal slice experiments (Tokarski *et al.*, 2003). One other electrophysiological effect identified for 5-HT<sub>7</sub> receptors was a weak but significant effect of 5-HT<sub>7</sub> and 5-HT<sub>2</sub> receptor activation at suppressing the perforant path input to CA1 pyramidal cells (Otmakhova *et al.*, 2005). 5-HT did not affect paired-pulse facilitation of this pathway, suggesting that the weak effect of 5-HT on suppressing the perforant pathway input is a postsynaptic rather than a presynaptic effect. The mechanism underlying this effect remains to be determined, as other receptors that act similarly on this pathway generally are coupled to G<sub>i</sub>/G<sub>o</sub> proteins such as mGlu2 and  $\alpha_2$ -adrenergic receptors. However, the general effect of 5-HT<sub>7</sub> receptor activation in the hippocampus appears to be an increase in the excitability of CA1 and CA3 pyramidal cells.

### Thalamic 5-HT<sub>7</sub> receptors

Another region where an electrophysiological effect of the 5-HT<sub>7</sub> receptor is well-characterized from both pharmacological and physiological standpoints is the anterodorsal nucleus (ADn) of the thalamus (Chapin and Andrade, 2001a, 2001b). 5-HT<sub>7</sub> receptor agonism exerts an excitatory effect (depolarization or inward current associated with modulation of an I<sub>h</sub> current) on the glutamatergic cells of the ADn of the thalamus. Pharmacological characterization was aided by a greater potency (18-fold) of 5-CT than 5-HT and blockade by both mesulergine (using Schild analysis) and the potent, selective 5-HT<sub>7</sub> receptor antagonist SB-269770. Other 5-HT agonists (e.g., DOI for 5-HT<sub>2A/2C</sub> receptors) did not induce an inward current, similar to 5-HT. Furthermore, 8-OH-DPAT induced weak induction of an inward current as well as blocking the effect of 5-HT, consistent with a partial agonist action for this compound at 5-HT<sub>7</sub> receptors. These findings build on the importance of this receptor for controlling hippocampal physiology, as these ADn neurons project to the retrosplenial granular cortex and receive afferents from the subiculum (including the pre- and parasubiculum) (Steriade *et al.*, 1997).

### Antidepressants modulate hippocampal 5-HT<sub>7</sub> receptors

A differential action of antidepressant drugs and electroconvulsive shock (ECS) has been found for the excitatory 5-HT<sub>7</sub> responses in the rat hippocampal CA3 field. Repeated daily treatment for 2 weeks with either the SSRI citalopram or the tricyclic antidepressant imipramine attenuated the 5-CT-induced increase in bursting frequency of CA3 pyramidal cells recorded from hippocampal slices (Toharski *et al.*, 2005). In contrast to the monoamine reuptake inhibitors, electroconvulsive shock enhanced the 5-HT<sub>7</sub> receptor-mediated enhanced epileptiform activity from extracellular recordings of CA3 pyramidal cells (Pitra *et al.*, 2007).

### Other 5-HT<sub>7</sub> receptor mediated responses

Another region where 5-HT<sub>7</sub> receptors appear to play an important role is in the suprachiasmatic nucleus, an important regulatory center of circadian physiology. For example, activation of 5-HT<sub>7</sub> receptors by 5-HT for cultured suprachiasmatic neurons is able to inhibit GABA-activated currents (Kawahara *et al.*, 1994). This response is also modulated by cAMP, as expected for a 5-HT<sub>7</sub> receptor. However, other 5-HT receptors are also involved in altering suprachiasmatic neuron physiology, including 5-HT<sub>2A/2C</sub> receptors.

Activation of both 5-HT<sub>7</sub> receptors and other 5-HT receptors appears to contribute to depolarizing effects in a number of different cellular compartments throughout the brain. For example, 5-HT<sub>7</sub> responses in the subthalamic nucleus and the globus pallidus were discussed above in the section on 5-HT<sub>1A</sub> receptors. The presence of 5-HT<sub>7</sub> receptors on striatal cholinergic interneurons is also discussed above in the section on 5-HT<sub>6</sub> receptors.

### Summary

One of the most remarkable features of psychopharmacology over the past 25 years has been the failure of selective 5-HT receptor agonists and antagonists to take their place in the armamentarium of psychotherapeutic drugs. We continue to have little understanding regarding which of the 5-HT receptors play a critical positive and negative role in mediating the effects of SSRIs and SNRIs in mood and anxiety disorders. Beyond a contribution for 5-HT<sub>2A</sub> receptors in mediating some of the actions of atypical antipsychotics, the contributions played by other 5-HT receptors in treating psychotic disorders (5-HT<sub>2C</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub>) remains uncertain. Certainly, the efficacy of selective 5-HT<sub>2A</sub> receptor antagonists for schizophrenia

(activity of M100907 and eplivanserin intermediate between placebo and haloperidol) and 5-HT<sub>1A</sub> receptor agonists for mood and anxiety disorders remains limited. The relative lack of success in converting agonists or antagonists highly selective for individual 5-HT receptor subtypes into effective novel therapeutic agents increases the need for translating the interactions between different 5-HT receptors and the serotonin transporter or between different 5-HT receptors and glutamate and GABA receptor subtypes to paradigms exploring the complexity of these interactions at higher levels of organization, such as oscillatory behavior of circuits, sleep and arousal processes, and behaviors closely linked to limbic-related macrocircuits.

# Tryptophan Hydroxylase and Serotonin Synthesis Regulation

Hiroyuki Hasegawa<sup>\*,1</sup> and Kazuhiro Nakamura<sup>2</sup>

<sup>1</sup>*Department of Biosciences, Teikyo University of Science and Technology, Uenohara, Japan*

<sup>2</sup>*Department of Pathology, Juntendo University School of Medicine, Tokyo, Japan*

**Abstract:** Potential determinants of existing tryptophan hydroxylase (TPH) activity *in vivo* are (1) a supply of tryptophan via the tryptophan transporter, (2) *de novo* synthesis of tetrahydrobiopterin and efficient regeneration of this coenzyme, and (3) iron metabolism. TPH is an iron protein. Iron binding is relatively strong in TPH2, while it is very weak in TPH1. Owing to the poorly liganded iron of TPH, various complexities arise. Irreversible inactivation of TPH and neural deterioration seem to be caused by an H<sub>2</sub>O<sub>2</sub> reaction with non-liganded or poorly liganded Fe<sup>2+</sup>. Within the cell, the amount of ferrous iron available to TPH is below saturation. The metabolism of iron may control serotonin production by attenuating actual TPH activity in the cell interior. Phosphorylation of TPH was studied in terms of its functional aspects with the use of brain TPH, while the identification of phosphorylation sites was mainly conducted on the basis of the amino acid sequence of TPH1. Protein turnover is cell-type specific in terms of its machinery, and its regulation is one of the major post-translational modifications of a protein. TPH degradation is likely linked to protein phosphorylation. Functionally, TPH, the rate-limiting enzyme in serotonin biosynthesis, is involved in neural development, which likely affects animal behaviors in the adult stages. Future studies will define the sensitive period during development when TPH activity is required for the fine-tuning of neuronal organization that is responsible for each behavior in the adult.

**Keywords:** iron protein, tetrahydrobiopterin, proteasome, hydroxyl radical, chelatable iron, iron deficiency, neural development, behavior, psychiatric disorder.

**Abbreviations:** TPH, tryptophan hydroxylase; 5-HT, 5-hydroxytryptamine (serotonin); 5-HTP, 5-hydroxy-L-tryptophan; AADC, aromatic L-amino acid decarboxylase; DHPR, dihydropteridine reductase; DHFR, dihydrofolate reductase; TH, tyrosine hydroxylase; PAH, phenylalanine hydroxylase; DTT, dithiothreitol; MDMA, 3,4-methylenedioxymethamphetamine; PCPA, para-chlorophenylalanine; PPI, prepulse inhibition.

## Serotonin biosynthesis

Serotonin (5-HT) is synthesized from L-tryptophan by a two-step enzyme reaction (Figure 1):

Reaction (1) is catalyzed by tryptophan hydroxylase (TPH; 1.14.16.4), and reaction (2) by aromatic-L-amino acid decarboxylase (AADC; EC 4.1.1.28). Among the serotonin-producing cells, tryptophan hydroxylase is expressed by such cells as serotonin-secreting neurons in the central nervous system and enteric neural plexus, enterochromaffin cells of the gastrointestinal mucosa, mast cells of various connective tissues, and pinealocytes of the pineal gland. A high concentration of 5-HT in these tissues is not always an indication of a strong expression of TPH. Platelets are an extreme example of this. They are the largest 5-HT carrier in the body, but hardly synthesize 5-HT at all. Instead, they take it up from the blood stream. Most 5-HT in the blood is secreted by the enterochromaffin cells of the gastrointestinal tract. Since the tissue level of 5-HT is maintained by a counterbalance between its production and release, it cannot be used to determine how rapidly 5-HT is regenerated unless the steady state is interrupted. In a classic challenge to this line of thought (Koe and Weissman, 1966), it was reported that the half-decay time of 5-HT in rat brain was about 12 hours

**Figure 1** Biosynthesis of serotonin from tryptophan. Serotonin (5-HT, 5-hydroxytryptamine) is synthesized from L-tryptophan by a two-step enzyme reaction. Tryptophan hydroxylase (TPH) requires molecular oxygen ( $\text{O}_2$ ) and tetrahydrobiopterin ( $\text{BH}_4$ ) as a co-substrate. The enzyme has an absolute requirement for ferrous iron ( $\text{Fe}^{2+}$ ). The reaction product, 5-hydroxy-L-tryptophan (5-HTP), is converted to serotonin by aromatic L-amino acid decarboxylase (AADC).

while that in the blood was about 3 days, the authors having arrived at their determinations by arresting the TPH reaction with high doses of p-chlorophenylalanine (PCPA), a pseudo-irreversible inhibitor of TPH. Neural 5-HT levels are relatively low compared with levels in peripheral organs such as the pineal gland and gastrointestinal mucosa, but production and utilization of 5-HT in the brain is much more rapid than all such tissues in the periphery.

AADC is the same entity as 'dopa decarboxylase', which catalyzes decarboxylation of dihydroxyphenylalanine (DOPA) in the production of catecholamines such as dopamine, noradrenaline and adrenaline (Lovenberg *et al.*, 1962; Christenson *et al.*, 1972). The enzyme is a homo-dimer containing one catalytically active pyridoxal 5'-phosphate per subunit (PALP-enzyme, or B6-enzyme) and catalyzes the decarboxylation of 5-HTP, yielding 5-HT in serotonin-producing cells (Voltattorni *et al.*, 1971). However, the enzyme AADC is not responsible for histamine production, which is catalyzed by the other PALP enzyme, histidine decarboxylase (HDC; EC 4.1.1.22). Distribution of AADC has been known to be much wider than that of tyrosine hydroxylase or TPH. In histochemical studies, many secretory cells derived from embryonic neural crest cells have been recognized as APUDs (members of the 'amine-precursor uptake and decarboxylation series'), which are characterized by monoamine accumulation when the precursor, dopa or 5-HTP, is supplied, and it is possible that these cells might express AADC. One idea that has been gaining support is that AADC is not only distributed non-specifically but also expressed in abundance. However, cellular levels of 5-HTP, the AADC substrate, are roughly 25–30 percent those of 5-HT on a molar basis in whole brains of mice, suggesting that this enzyme is not always furnished in excess. It is also noteworthy that 5-HT is condensed in secretory (particle) vesicles in 5-HT-secreting cells. These

cells are usually furnished with the uptake transporter VMAT which is not bidirectional – i.e., not capable of outward movement. Since 5-HTP is bidirectionally relocated across the cell membrane, it is probably delivered via the amino acid transporter for tryptophan.

## Background of tryptophan hydroxylase

### Factors responsible for TPH activity in vivo

Tryptophan hydroxylase is a biopterin-dependent monooxygenase (Kaufman, 1962). Monooxygenases catalyze reactions by oxygenating their substrate with one atom of oxygen following cleavage of the double bond of dioxygen with two electrons donated by a co-substrate. These reactions require assistance from transient metals such as iron. In the TPH reaction, one oxygen atom is inserted into the indole ring at C(5) of tryptophan and the other oxygen is accepted by  $\text{BH}_4$  (Figures 1 and 2) yielding 4a-hydroxy- $\text{BH}_4$ . The hydroxylase engages in three enzyme reactions all connected to the biopterin cofactor:

TPH reaction (1) produces 5-hydroxy-L-tryptophan (5-HTP) and 4a-hydroxy- $\text{BH}_4$  (pterin-4a-calbinolamine derivative of  $\text{BH}_4$ ). Reaction (2) proceeds spontaneously or can be catalyzed by a dehydrating enzyme,<sup>1</sup> and reaction (3) proceeds by dihydropteridine reductase (DHPR; EC 1.6.99.7) (Kaufman, 1964). The total reaction process is as follows,

**Figure 2** Recycling of BH<sub>4</sub>, the essential coenzyme. BH<sub>4</sub> works as a two-electron donor in the TPH reaction. The reaction product is 4a-hydroxy-BH<sub>4</sub> (pterin-4a-carbinolamine) which liberates H<sub>2</sub>O, yielding quinonoid dihydrobiopterin (qBH<sub>2</sub>). qBH<sub>2</sub> is reduced back to BH<sub>4</sub> by the action of dihydropteridine reductase (DHPR). qBH<sub>2</sub> spontaneously converts to 7,8-dihydrobiopterin (BH<sub>2</sub>). BH<sub>2</sub> can be recycled by dihydrofolate reductase (DHFR) to BH<sub>4</sub>, but DHFR is not always present in a large enough amount to convert BH<sub>2</sub> in 5-HT-producing cells. Hence, conversion of qBH<sub>2</sub> to BH<sub>2</sub> is virtually synonymous with inactivation of BH<sub>4</sub>.

where a catalytic amount of BH<sub>4</sub> functions as an essential coenzyme for the TPH reaction in the cell:

Hence, TPH requires three substrates for its hydroxylation: (1) dioxygen, (2) tryptophan, and (3) tetrahydrobiopterin (BH<sub>4</sub>). Dissociable ferrous iron is also a limiting component of the enzyme reaction under the actual intracellular conditions.

1. O<sub>2</sub> is most actively reduced in mitochondria to H<sub>2</sub>O; however, a considerable portion of O<sub>2</sub> is incompletely reduced, yielding O<sub>2</sub><sup>•-</sup> and H<sub>2</sub>O<sub>2</sub>. The reduced oxygen may be benign as long as ferrous iron is absent. However, TPH is highly susceptible to H<sub>2</sub>O<sub>2</sub>, presumably due to its poor liganding of Fe<sup>2+</sup> (Kell, 2009), as discussed below. This might be the key to understanding various problems related to TPH, including cytotoxic events caused by drugs targeting 5-HT-producing cells.

2. L-Tryptophan, an essential amino acid for humans, is supplied to the brain through the blood circulation. Supplementation with tryptophan increases production of serotonin in the brain,<sup>2</sup> suggesting an insufficient supply of tryptophan as far as the central nervous system (CNS) is concerned (Koe and Weissman, 1966; Fernstrom and Wurtman, 1971).
3. BH<sub>4</sub> in the brain is believed to be synthesized in the CNS. The concentration of BH<sub>4</sub> as a TPH substrate is not at saturation level in the CNS (Miwa *et al.*, 1985), hence the BH<sub>4</sub> level would be directly responsible for 5-HT production.

Post-translational modification and TPH degradation would control 5-HT biosynthesis as well as TPH gene expression. The following sections will focus on cellular mechanisms for maintaining cofactor levels, as well as on the involvement of (1) BH<sub>4</sub> and (2) ferrous iron. Then, the focus will shift to (3) enzyme stability, which is closely related to incomplete liganding with iron, followed by a

discussion of (4) phosphorylation and, finally, (5) TPH degradation.

### *Two isoforms of tryptophan hydroxylase*

Tryptophan hydroxylase exists as two isoforms, TPH1 and TPH2, which are encoded on two independent genes. The molecular identity of the brain type of TPH was unknown for the 15 years until the discovery of the second gene encoding TPH2.

In the late 1960s, tryptophan hydroxylase was first characterized in extracts from a neonatal tissue of peripheral origin (Hosoda and Glick, 1965; Lovenberg *et al.*, 1965) and from brain tissue (Grahame, 1967; Lovenberg *et al.*, 1967). The peripheral TPH and the brain enzyme were distinguished as different entities based on details of kinetic parameters and physicochemical properties especially reflecting its stability, as well as by immunoreactivity (Kuhn *et al.*, 1980a; Nakata and Fujisawa, 1982a, 1982b; Hasegawa *et al.*, 1987). However, the molecular basis of their separate status – i.e., the difference in their amino acid sequences – was not clearly recognized until 2003, when the second gene was found that represented the major portion of the brain enzyme (Cote *et al.*, 2003; Walther *et al.*, 2003; Zhang *et al.*, 2004).

Before gene cloning came into common use, an enzyme was characterized using the purified protein. In the case of TPH, however, the enzymes from both the peripheral organs and the brain were very difficult to purify, largely due to their<sup>3</sup> unusual instability (Ichiyama *et al.*, 1974; Kuhn *et al.*, 1980b; Cash, 1998). Even when the purification method was established in the early 1980s (Nakata and Fujisawa, 1982a, 1982b; Cash *et al.*, 1985), this extreme instability hampered any detailed characterization of the enzyme. The cloning of the cDNA could have facilitated characterization of the relevant enzyme. TPH cDNA was first cloned in 1987 from a rabbit peripheral organ, the pineal gland (Grenett *et al.*, 1987). Since then, many cDNAs have been cloned from various libraries of other sources including the brain (Darmon *et al.*, 1988; Boularand *et al.*, 1990; Stoll *et al.*, 1990; Kim *et al.*, 1991; D'Sa *et al.*, 1996; Florez *et al.*, 1996; Kowlessur and Kaufman, 1999). The full-length amino acid sequence of TPH has not been determined with purified enzyme, and hence has never been compared with the sequence deduced from the cDNA. Although multiple splicing was noted in the non-coding regions (Darmon *et al.*, 1988; Boularand *et al.*, 1995), they all included a homologous ORF, and the authors did not explain the known difference between the brain TPH and the peripheral enzyme. It was speculated that

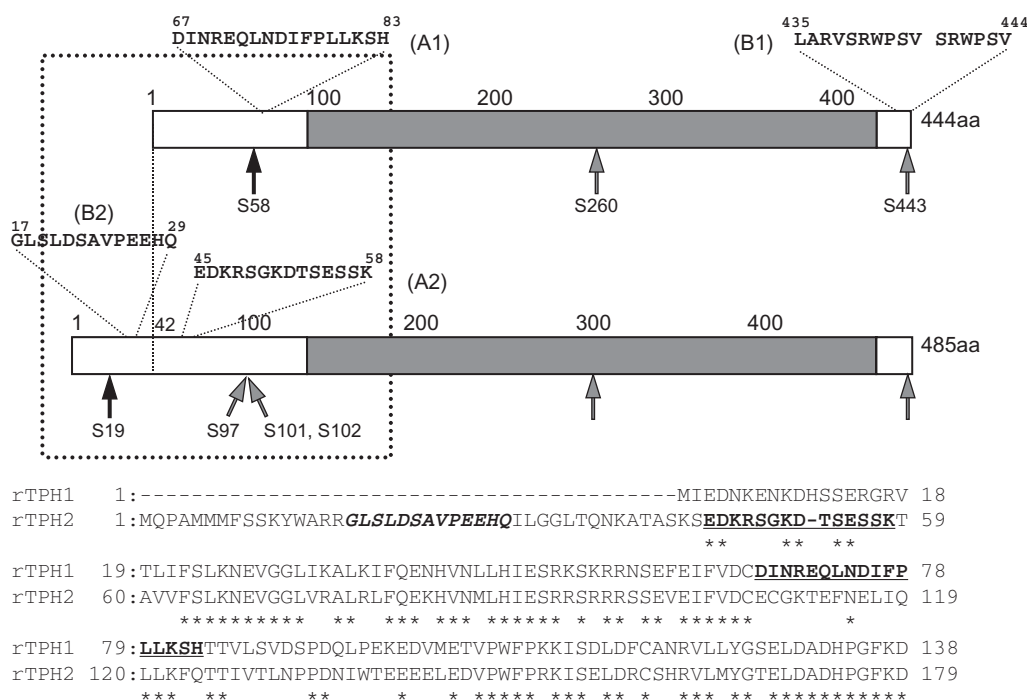

the difference arose from region-specific post-translational modification (Kim *et al.*, 1991), but no conclusive evidence was provided. Many researchers investigated 5-HT synthesis in the brain using probes based on the commonly cloned cDNA, which we now know to be TPH1, a minor portion of TPH in the brain but a major protein in the periphery. The molecular identity of the brain counterpart was established in 2003, and the new isoform was termed TPH2 (Cote *et al.*, 2003; Walther *et al.*, 2003; Zhang *et al.*, 2004). Thus, research on 5-HT-production in the brain had a very arduous 15 years in terms of the molecular aspects of neuronal TPH.

The amino acid sequence of TPH1 (444 amino acids) (Grenett *et al.*, 1987; Darmon *et al.*, 1988) is highly preserved in the amino acid sequence of TPH2 except for an additional 41 amino acid peptide at the N-terminal (485 amino acids (Walther *et al.*, 2003)), as depicted in Figure 3. They are both composed of three major domains; a C-terminal tetramerization sequence, a central catalytic body, and an N-terminal regulatory peptide. In addition, both are essentially soluble enzymes and behave as a tetramer (Nakata and Fujisawa, 1981, 1982a). The expression of TPH2 is predominant in the neurons and that of TPH1 in the peripheral organs, including the pineal gland. However, the minor expression of either enzymes in the other's favored location has also been shown (Nakamura *et al.*, 2008). TPH1 is the primary form and expresses earlier in neural development (Nakamura *et al.*, 2006a; Nakamura and Hasegawa, 2007). Studies on the local and temporal distribution of the two isoforms would lead to further understanding of their roles in particular functions as well as in neural development. In this context, the use of mono-specific antibodies raised against a distinctive region(s) of the respective TPH (Sakowski *et al.*, 2006; Nakamura *et al.*, 2008) (Figure 3) would allow researchers to distinguish between the two isoforms, and would be a powerful tool for further investigation.

### *BH<sub>4</sub> requirement*

BH<sub>4</sub> is an essential coenzyme for both tryptophan hydroxylase and tyrosine hydroxylase. BH<sub>4</sub> regulates the rate of 5-HT production.

Cells engaged in production of 5-HT contain a catalytic amount of BH<sub>4</sub>. Since the intracellular concentration of BH<sub>4</sub> is not likely to be at saturation level (Miwa *et al.*, 1985), which is around or lower than the  $K_m$  of TPH (roughly 20–30  $\mu$ M), TPH exerts only a fraction of its potential activity ( $V_{max}$ ). When BH<sub>4</sub> is delivered directly to the brain, by microdialysis infusion (Miwa *et al.*, 1985), by direct injection into the brain (Kapatos *et al.*, 1982), or by immersion of brain slices into 6RBH<sub>4</sub>-containing

**Figure 3** Schematic diagram of determined or putative phosphorylation sites of tryptophan hydroxylase TPH1 and TPH2. In TPH, three domains from the N-terminal adjacent to the C-terminal are known to be regulatory, catalytic (gray) and tetramer-forming, with amino acid sequences that are well conserved (marked with an asterisk\*), while 41 additional peptides are unique to TPH2. A1 and A2 denote peptides employed in raising antisera that exclusively distinguish TPH1 and TPH2, respectively (bold underlined) (Nakamura *et al.*, 2008). B1 and B2 similarly represent mono-specific antisera (bold italics) (Sakowski *et al.*, 2006). Numbered serine residues denote determined or putative phosphorylation sites (references in text).

saline (Sawada *et al.*, 1986), TPH activity in the treated rat brain or tissues significantly increased, which was determined by a metabolic assay using the decarboxylase inhibitor NSD-1015 or NSD-1055. Similar enhancement was described in a report on RBL2H3 cells under monolayer culture expressing the peripheral type of TPH; cellular TPH activity was stimulated two-fold when the level of intracellular BH<sub>4</sub> was increased by means of sepiapterin administration<sup>4</sup> (Hasegawa *et al.*, 1999). Hence, serotonin-producing cells do not use up their full potential TPH activity (for review, see Sawada and Nagatsu, 1988). The concentration of the active co-substrate, BH<sub>4</sub>, is maintained mainly through recycling (Figure 2). As an analogy to the phenylalanine hydroxylase reaction in the liver, the primary product of BH<sub>4</sub> in the TPH reaction might be an unstable 4a-hydroxy-BH<sub>4</sub>, pterin-4a-carbinolamine (Curtius *et al.*, 1993). Pterin-4a-carbinolamine could be dehydrated by an enzyme, pterin-4a-carbinolamine dehydratase (PCD; EC 4.2.1.96), but this protein is not likely expressed in the brain (Davis *et al.*, 1992; Lei and Kaufman, 1999). PCD/DCoH is a bifunctional protein, the DCoH portion serving as a cofactor regulating dimerization of the hepatic nuclear factor, NHF1, a homeodomain transcription factor (Citron *et al.*, 1992). However, this

pterin intermediate is quite unstable at a neutral pH and dehydration of pterin-4a-carbinolamine might take place, spontaneously producing quinonoid dihydrobiopterin (qBH<sub>2</sub>) (Kaufman, 1976). In the recycling system, the actual concentration of BH<sub>4</sub> is determined by a balance between reducing DHPR activity and BH<sub>4</sub>-oxidizing activity. Unless sufficient DHPR is furnished within the cell, conversion of qBH<sub>2</sub> to the more stable 7,8-BH<sub>2</sub> will occur spontaneously; the half decay time of qBH<sub>2</sub> was estimated to be 1.8 minutes (Watabe, 1978). The enzyme DHPR prefers NADH to NADPH as its co-substrate; however, there is a ready availability of NADPH in the cytosol of living cells, which could be much more abundant than that of NADH.<sup>5</sup> Hence, an insufficient supply of NADPH might allow qBH<sub>2</sub> to convert to the inactive 7,8-BH<sub>2</sub>, and 7,8-BH<sub>2</sub> could then be salvaged by reaction (4) catalyzed by dihydrofolate reductase (DHFR; EC 1.5.1.3) (Kaufman, 1967; Nichol *et al.*, 1983):

The enzyme catalyzes reduction of the 7,8-dihydroform of both conjugated and unconjugated pterin<sup>6</sup> using NADPH as the coenzyme. This enzyme is widely

distributed in most tissues and hence the amount of DHFR in the body as a whole is sufficient for reducing 7,8-BH<sub>2</sub> back to active BH<sub>4</sub> for economical recycling of BH<sub>4</sub> (Sawabe *et al.*, 2004); however, the level of DHFR is not high enough to replace DHPR in supporting local monoamine production.<sup>7</sup> DHFR was reported not to distribute to neurons in a high enough amount to salvage *in situ* oxidized BH<sub>4</sub> for the local production of monoamines especially in the CNS (Bonafe *et al.*, 2001). The key to explaining these contradictory observations could be the short life of qBH<sub>2</sub> as mentioned above ( $T_{1/2} = 1.8$  min). When the quantity of DHPR is insufficient for reducing qBH<sub>2</sub> before qBH<sub>2</sub> conversion to 7,8-BH<sub>2</sub> within a short period, as determined by the short half-life, the formed 7,8-BH<sub>2</sub> exits from the cell into the body circulation.<sup>8</sup> BH<sub>4</sub> is virtually impermeable across the plasma membrane and there are no known transporters to date, but its oxidized form, 7,8-dihydrobiopterin (7,8-BH<sub>2</sub>), is somewhat more permeable. In this context, the conversion of qBH<sub>2</sub> to 7,8-BH<sub>2</sub> might be the major route by which BH<sub>4</sub> is withdrawn from the cell. Hence, the production of 7,8-BH<sub>2</sub> in the cell could be accounted for by the inactivation of BH<sub>4</sub> – that is, a local loss of active BH<sub>4</sub> in the cell. DHPR is therefore fully responsible for the intracellular recycling of BH<sub>4</sub> through the reduction of qBH<sub>2</sub>.

As mentioned above, BH<sub>4</sub> levels in the cell determine the rate of 5-HT production. However, the mechanism by which BH<sub>4</sub> is maintained in the cell at a given level which is obviously higher than the extracellular concentration remains unclear. High-affinity uptake was suggested (Hasegawa *et al.*, 2007), but the evidence is not yet conclusive. The biosynthesis rate is counterbalanced with the loss of BH<sub>4</sub>, essentially by conversion of qBH<sub>2</sub> to 7,8-BH<sub>2</sub> and the leaking out of the latter. The turnover rate expressed by the half-life of BH<sub>4</sub> was 120 to 230 minutes in monoamine-producing cells under monolayer culture (Hasegawa *et al.*, 2005). The rate was estimated by the initial decrease in BH<sub>4</sub> after the addition of DAHP (2,4-diamino-6-hydroxypyrimidine), an inhibitor of GPT-cyclohydrolase I. BH<sub>4</sub> supplementation can be achieved by administering 7,8-BH<sub>2</sub> or, preferably, sepiapterin (Sawabe *et al.*, 2008). If the deficiency is in the CNS, however, peripheral administration of BH<sub>4</sub> is very inefficient due to the presence of the blood–brain barrier (BBB). The mechanism for rejection of BH<sub>4</sub> at the BBB is not known to date. BH<sub>4</sub> supplementation has only ineffectively raised 5-HT production (Brand *et al.*, 1996). Moreover, it has not come into common use owing to the rapid renal clearance<sup>9</sup> that takes place when it is exogenously supplied, in addition to its poor ability to cross the BBB. Oral supplementation with BH<sub>4</sub> has been prescribed only for BH<sub>4</sub>-deficient patients whose conditions would otherwise be very serious. If there were means to overcome these obstacles,

BH<sub>4</sub> supplementation could be a potent therapy in the future for stimulating 5-HT synthesis.

### TPH as an iron enzyme

TPH is an iron protein. Iron binding is relatively strong in TPH2 while it is very weak in TPH1.

The biopterin-dependent aromatic amino acid hydroxylases, phenylalanine-, tyrosine- and tryptophan-hydroxylase, share many structural homologies, and they all require bound iron for their catalytic functions. Hence, a brief comparison of these three hydroxylases would help us to understand their intrinsic natures. Phenylalanine hydroxylase (PAH; EC1.14.3.1) carries the most tightly bound iron, and the enzyme is active *in vitro* when purified without iron enrichment (Fisher *et al.*, 1972; Gottschall *et al.*, 1982). However, according to Shiman and Jefferson (1982), a large proportion of rat liver PAH (20–45 percent) is in an inactive state due to an iron vacancy, which represents a state of dynamic equilibrium controlled by the metabolism of hepatic iron. Tyrosine hydroxylase (TH; EC1.14.16.2) requires iron enrichment for an appreciable reaction *in vitro*. TH was found to contain iron at a less than stoichiometric concentration when purified to homogeneity from bovine adrenal medulla (Haavik *et al.*, 1988). Recombinant human TH isoforms, the alternative mRNA splicing products TH1–TH4, each expressed in *E. coli* and purified without iron enrichment in the presence of 1  $\mu$ M EDTA, contained little iron, amounting to less than 0.1 atom/subunit. These isoforms were almost inactive, and required Fe<sup>2+</sup> plus mercaptan for their enzyme activity (Haavik *et al.*, 1991). The status of iron binding is distinctive in tryptophan hydroxylase isoforms TPH1 and TPH2. Using rat brainstem, Nakata and Fujisawa purified TPH to around 5000-fold greater than the amount in crude extracts by maintaining a concentration of 50- $\mu$ M EDTA almost throughout the entire purification. The purified enzyme was still active without iron enrichment, although it was ‘activated’ several fold by incubation with Fe<sup>2+</sup> (Nakata and Fujisawa, 1982a). The stable iron-binding of the brain TPH was also observed in another laboratory; in these assays, the enzyme did not lose its activity even after a 17-h incubation with 100- $\mu$ M EDTA at 4°C (Cash *et al.*, 1985). In contrast, the peripheral type of TPH, TPH1, obtained from mouse mastocytoma P-815, contained less than a stoichiometric amount of iron (0.05 atom/subunit). In addition, it was virtually inactive unless Fe<sup>2+</sup> was added together with the appropriate mercaptan as described below (Hasegawa and Ichiyama, 2005). Iron-free TPH1 was available just by mixing with EDTA (100  $\mu$ M) and successively removing the chelator by gel filtration.

In this context, TPH2 appeared to have bound iron with relatively high affinity, while TPH1 was the least stable in terms of iron-binding among the aromatic amino acid hydroxylases so far examined. In any case, TPH has an iron-binding site composed of neighboring His, and Glu at the bottom of the tryptophan-binding groove in the 3D-structure, which was illustrated using recombinant TPH1 crystallized as a stable but inactive complex in the presence of  $\text{Fe}^{3+}$  and 7,8-BH<sub>2</sub> (Wang *et al.*, 2002).

#### *Activation of TPH, or restoration of the lost activity of TPH*

Owing to the poorly liganded iron of TPH, various complexities arose: reversible inactivation of TPH seems to be brought about by oxidation of  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$ .

TPH is quite unstable, whether in tissue extracts or as a purified preparation, and undergoes a serious loss in its activity under atmospheric conditions. A portion of the lost activity is restorable by an 'activation' procedure. The TPH reaction was carried out *in vitro* in the presence of  $\text{Fe}^{2+}$  and appropriate thiols such as 2-mercaptoethanol or DTT in an empirical effort to preserve the tetrahydropterin cofactor. Ichiyama's group developed a TPH assay that included a two-step incubation, anaerobic and aerobic, to 'activate' the enzyme and the subsequent TPH reaction, respectively (Ichiyama *et al.*, 1974). The procedure was very effective with most TPH preparations of peripheral origin, i.e., largely containing TPH1.<sup>10</sup> Anaerobicity was viewed as essential at that time, but it is actually unnecessary when more than 2mg/ml of catalase are included in the activation mixture. 'Activation' of the enzyme in the former incubation with ferrous iron (50 $\mu\text{M}$ ) and DTT (30mM) had to be separated from the enzyme reaction, they claimed, because the activation was a time-dependent process and its progress was interrupted when tryptophan was added. The activation process was completed within about 15 minutes. Several-fold higher activity was obtained with freshly prepared tissue extracts (Hasegawa *et al.*, 1987), and even more activity was achieved with purified enzyme which had lost activity during the purification procedure. A similar protocol was used for 'activation' of the brain enzyme. Activation (or recovery of lost activity) with the brain TPH required a prolonged incubation, 20–24h, under similar anaerobic conditions (Hamon *et al.*, 1978; Kuhn *et al.*, 1980b; Stone *et al.*, 1989a). These features of TPH activation (or restoration) suggested a homology between TPH1 and TPH2, but at the same time we noted a great difference in the rate of the process, presumably due to their respective iron-binding affinities, which differed by more than two orders of magnitude. Since the activation did not alter kinetic parameters of TPH of either the brain or peripheral enzymes except for the  $V_{\text{max}}$ , it is considered

that the procedure increased the number of active TPH molecules rather than altered the functional properties of the enzyme. The same activation procedure, i.e., treatment of the enzyme with ferrous iron and a thiol under anaerobic conditions, was employed in the restoration of the homologous hydroxylases TH (Okuno and Fujisawa, 1981; Haavik *et al.*, 1988; Ramsey *et al.*, 1995) and PAH (Fisher *et al.*, 1972) after *in vitro* iron deprivation. Furthermore, PAH inactivated by removal of iron from the liver under perfusion was also restored with a similar treatment *in vitro* (Shiman and Jefferson, 1982). However, the restoration conditions were similar to those employed in the restoration or activation of other non-heme iron proteins such as aconitase (Kennedy *et al.*, 1983) and phosphoenolpyruvate carboxykinase (Bentley and Lardy, 1977), suggesting common iron liganding behavior.

Since TPH is very fragile *in vitro*, it was uncertain for long time whether the inactivation, or activation, occurred only under cell-free conditions as an artifact or even whether it occurred *in vivo* as a physiological event. In this regard, an acute depression in TPH activity in rat brain after administration of 3,4-methylenedioxymethamphetamine (MDMA, single dose of 4–10mg/kg, i.p.) (Schmidt and Taylor, 1987) was reported as evidence that the 'inactivation' did indeed take place *in vivo*. Subsequently, it was demonstrated that the enzyme activity was recovered *in vitro* as well as *in vivo* (Stone *et al.*, 1989b). The *in vivo* recovery was not likely brought about by protein synthesis, because it took place even in rats whose protein synthesis was blocked by cycloheximide (1 mg/kg, i.p.), suggesting that the re-activation occurred through a molecular modification. The *in vitro* reactivation of TPH obtained from rats treated with MDMA or its metabolites was achieved by anaerobic incubation with  $\text{Fe}^{2+}$ /DTT (Elayan *et al.*, 1993). Thus, this iron-related inactivation and reactivation is considered to take place *in vivo*. *In vitro* inactivation of TPH (brain enzyme) was demonstrated by nitric oxide (NO) exposure (Kuhn and Arthur, 1996). NO-driven inactivation *in vitro* was analyzed using recombinant TPH1, and the inactivated enzyme was similarly recovered by anaerobic incubation with  $\text{Fe}^{2+}$  and a thiol compound such as DTT (Kuhn and Arthur, 1997). Since the *in vitro* inactivation was highly antagonized by thiols, it was considered to be caused by oxidation of protein sulfhydryl (Stone *et al.*, 1989a; Kuhn and Arthur, 1997). The reason for the need for a high concentration of thiols has been controversial (Hasegawa and Ichiyama, 2005). Nonetheless, the involvement of nitric oxide (NO) was evidenced by the *in vivo* depletion of TPH induced by MDMA treatment (Zheng and Laverty, 1998; Darvesh *et al.*, 2005). NO-mediated inactivation of TPH might be a key cause of the neurotoxicity of such drugs as MDMA or their metabolites.

### *Unusual instability of reversible or irreversible TPH inactivation*

Irreversible inactivation of TPH and neural deterioration seem to be caused by an  $\text{H}_2\text{O}_2$  reaction with non-liganded or poorly liganded  $\text{Fe}^{2+}$ .

The peripheral TPH, TPH1, was purified as an inactive but restorable form from bovine pineal gland (Ichiyama *et al.*, 1976) and mouse mastocytoma P815 (Nakata and Fujisawa, 1982b). In the case of brain TPH, its unusual instability has long hindered the progress in TPH research as a means of understanding the neural regulation of 5-HT production. The inactivation of TPH2 was slower than that of TPH1 but it was still very fast, which made purification difficult. Purification of the brain TPH was achieved by adding catalase to the enzyme solution (the enzyme to be purified had to be mixed with catalase for purification) (Nakata and Fujisawa, 1982a; Cash *et al.*, 1985). The instability was enhanced by the addition of  $\text{Fe}^{2+}$  and a reducing compound, such as ascorbate or mercaptan, in the presence of oxygen (Kuhn *et al.*, 1980b). The protective effect of catalase was remarkable,<sup>11</sup> suggesting involvement of  $\text{H}_2\text{O}_2$ . These features can be accounted for by the Fenton Reaction (Stadtman and Berlett, 1991; Wardman and Candeias, 1996). The key reactions in the TPH-inactivating system including  $\text{Fe}^{2+}$ , DTT,  $\text{BH}_4$ , and  $\text{O}_2$  might be the reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}_2$  and of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  and the subsequent formation of an activated oxygen (hydroxy radical  $\text{HO}^\bullet$  or ferryl ion  $\text{FeO}^{2+}$ ):

In the case of the reaction of free  $\text{Fe}^{2+}$  or its aquo-ion with  $\text{H}_2\text{O}_2$ , impairment of an amino acid by the activated oxygen would take place at random – i.e., non-specific with regard to the chemical modification site, comparable to the exposure of proteins to ionizing radiation (Stadtman and Berlett, 1991). Taking the short range of  $\text{HO}^\bullet$  free movement into account, the Fenton reaction with bound iron takes place in a site-specific manner (Stadtman and Oliver, 1991). The inactivation of TPH was efficiently prevented by the substrate, tryptophan, in a saturable manner (unpublished data). The allowance of  $\text{H}_2\text{O}_2$  access suggested that the  $\text{Fe}^{2+}$  was poorly liganded at the bottom of the active site as proposed by the crystallographic 3D structure (Wang *et al.*, 2002). This fact was consistent with the lack of protection by chemical  $\text{HO}^\bullet$  scavengers (Kuhn *et al.*, 1980b; Stadtman and Oliver, 1991; Cash, 1998). The oxidation of  $\text{Fe}^{2+}$  by  $\text{H}_2\text{O}_2$  providing  $\text{Fe}^{3+}$  results in TPH inactivation, as illustrated in Figure 4A. While oxidation of  $\text{Fe}^{2+}$  with  $\text{H}_2\text{O}_2$  efficiently inactivates TPH, this inactivation can be reactivated by removing  $\text{Fe}^{3+}$  and supplying ferrous iron  $\text{Fe}^{2+}$ . Simultaneously generated  $\text{HO}^\bullet$  attacks the amino acid at the active site,

although at less than 100 percent probability, leading to fatal inactivation of TPH, which is irretrievable on anaerobic incubation with  $\text{Fe}^{2+}$ /DTT.  $\text{H}_2\text{O}_2$  plays an essential role in both the reversible and irreversible inactivation of TPH; therefore, the scavenging of  $\text{H}_2\text{O}_2$  by catalase or glutathione peroxidase prevents this inactivation. In living cells, however,  $\text{H}_2\text{O}_2$  or its precursor  $\text{O}_2^{\bullet-}$  is continuously produced in normal mitochondria, accompanied by the reduction of  $\text{O}_2$  to water at a considerable rate (*ca.* 1–4 percent of  $\text{O}_2$  reduced). To add to our confusion, catalase resides in the peroxisome and not in the cytosolic space accommodating TPH. Considering that TPH levels are maintained in the cell, the following possibilities are suggested:

1. TPH is protected by an unknown enzyme(s) scavenging  $\text{H}_2\text{O}_2$  or  $\text{HO}^\bullet$
2.  $\text{Fe}^{2+}$  of native TPH *in vivo* is somehow in a more completely liganded form so that  $\text{H}_2\text{O}_2$  does not react to cause site-specific modification
3. The actual concentration of  $\text{Fe}^{2+}$  is much lower than under our experimental conditions ( $>10^{-5}$  M)
4. TPH is actually inactivated by  $\text{HO}^\bullet$  at a fast rate and turns over rapidly.

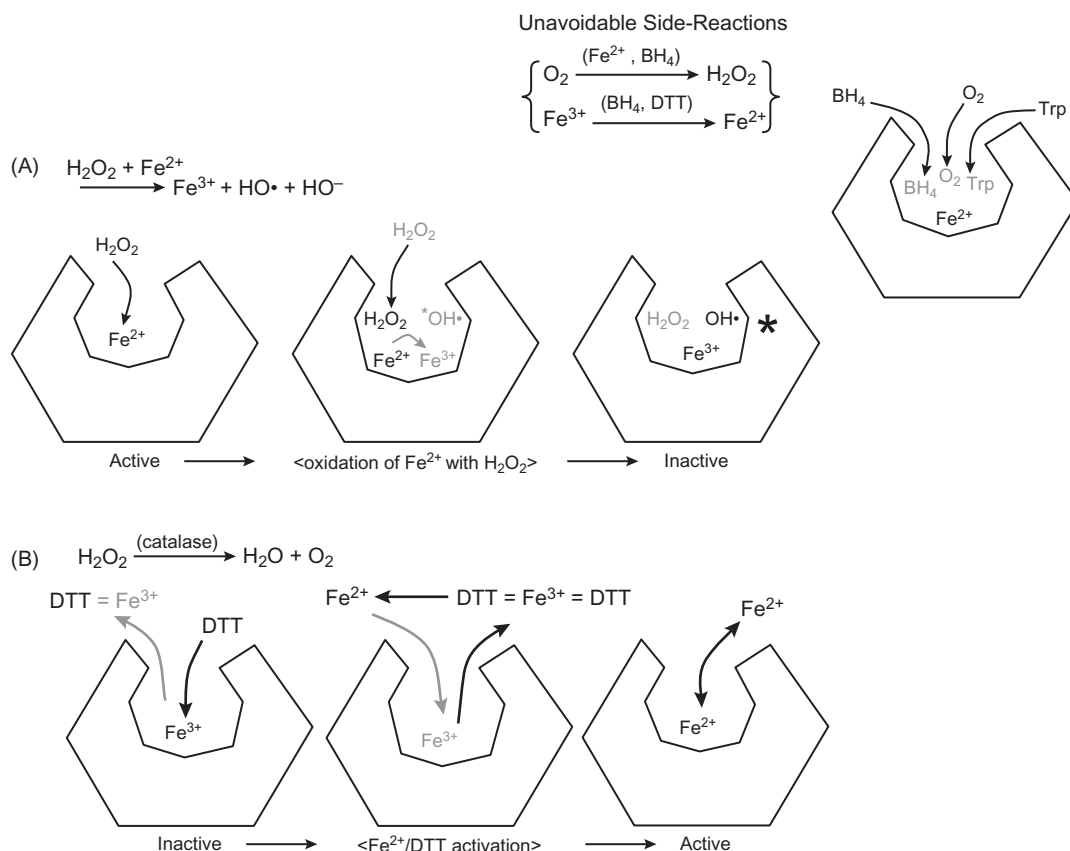

At present, we do not have any supporting evidence. With aconitase, another  $\text{H}_2\text{O}_2$ -sensitive and ' $\text{Fe}^{2+}$ /DTT-activated' non-heme iron protein, the degradation rate was reported to be enhanced by chemical modification caused by reactive oxygen radicals (Grune *et al.*, 1998), although the cytosolic concentration of chelatable  $\text{Fe}^{2+}$  might have been lower than  $10^{-6}$  M, as discussed below.

### *Unique iron requirement of TPH*

TPH1 activity has an absolute requirement for  $\text{Fe}^{2+}$ .  $\text{Fe}^{3+}$  antagonizes  $\text{Fe}^{2+}$ , and  $\text{Fe}^{3+}$ -bound TPH is inactive.

The method for TPH activation, anaerobic incubation with  $\text{Fe}^{2+}$  and DTT, was empirically established, but it proved to be useful in a wide range of applications involving pterin-dependent hydroxylases and other non-heme iron proteins, as mentioned above. However, the duration required for its completion differed with each application (probably due to differences in liganding stability). The activation mechanism for one enzyme may often serve as a guide for understanding others. With the use of TPH1 purified from mouse mastocytoma P815, 'DTT-activation' was examined and a mechanism was proposed (Hasegawa and Ichiyama, 2005). Since TPH1 and TPH2 have not been compared in the literature as yet, the core of the work with TPH1 described below could represent a sort of case study. The iron content of purified TPH1 was far less than the expected stoichiometry (0.05 atm/subunit), even though

**Figure 4** Schematic representation of mechanisms for inactivation of tryptophan hydroxylase and its reactivation by DTT. In enzyme activation and subsequent reaction, or even during storage, TPH is unavoidably exposed to  $\text{Fe}^{2+}$  and dioxygen in the presence of high concentrations of reducing compounds – conditions favorable for the Fenton reaction. (A) The Fenton reaction oxidizes  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  and generates  $\text{HO}\cdot$ . TPH is inactivated irreversibly from an occasional site-directed attack by  $\text{OH}\cdot$  at the active-site amino acid residue. (B) DTT, an  $\text{Fe}^{3+}$ -chelating thiol, masks  $\text{Fe}^{3+}$  and removes it from the inactive TPH resulting in the enzyme reactivation. The presence of  $\text{H}_2\text{O}_2$  is key, but  $\text{H}_2\text{O}_2$  can be scavenged by a high concentration of catalase of probably more than 4 mg/ml.

the purification was achieved by one-step affinity chromatography with a yield of 50–70 percent. It appeared as if iron was not essential for the enzyme activity, because the enzyme was fully active as long as it was incubated with DTT but without the addition of exogenous iron. However, to confuse matters, the iron-free apo-enzyme assayed had an absolute requirement for  $\text{Fe}^{2+}$  which was not replaceable even with  $\text{Fe}^{3+}$  and even in the absence of DTT (Hasegawa and Ichiyama, 1986). Special care was taken to prevent contamination by ambient iron. The point of confusion was explained by a ‘shared use of exiting iron’<sup>12</sup> based on the rapid exchange of dissociable  $\text{Fe}^{2+}$  at the effective concentration required by the enzyme. The minimum effective concentration of  $\text{Fe}^{2+}$  on apo-TPH for the enzyme to be active was around  $10^{-10}$  M (Hasegawa and Ichiyama, 2005), which was estimated using an  $\text{Fe}^{2+}$ -ion buffer system<sup>13</sup> TPH had no activity in the presence of  $\text{Fe}^{2+}$  at an estimated concentration of  $1.8 \times 10^{-12}$  M (metal buffer:

0.1 mM  $\text{Fe}^{2+}$  + 1 mM EDTA at pH 6.7). On the other hand, TPH showed full activity (5-HTP formation:  $5 \mu\text{mol}/\text{min}$  per mg) in the presence of  $8.7 \times 10^{-9}$  M  $\text{Fe}^{2+}$  (metal buffer: 0.5 mM  $\text{Fe}^{2+}$  + 1 mM EGTA at pH 6.7). The stability constant ( $\text{Log } K_{\text{ML}}$ , L denotes TPH) falls between 8 and 12.  $\text{Fe}^{3+}$ -removal from inactive TPH was achieved by incubation with metal-chelating sulfhydryl compounds with a common structure,  $\text{HSCCOH}$  or  $\text{HSCCNH}$ , and either was replaceable with EGTA. 8-Mercaptoquinoline, an  $\text{Fe}^{2+}$ -chelating thiol, did not function in this case, and potential SS breakers such as  $\text{S}^{2-}$  or tri-*n*-butylphosphine failed to activate the enzyme. The concentration of the reagent required for effective activation of TPH was much higher than that expected for disulfide bond cleavage, suggesting that DTT was unlikely to be a disulfide bond breaker for which a 30-fold molar excess was thought to be sufficient. Thus, the ‘ $\text{Fe}^{2+}$ /DTT activation’ can be understood as illustrated in Figure 4B: DTT preferably binds

to free  $\text{Fe}^{3+}$  and prevents it from binding to TPH, and the removal of  $\text{Fe}^{3+}$  from TPH by a high concentration of DTT takes place simultaneously with the regeneration of  $\text{Fe}^{2+}$ . In practice, an *in vitro* reaction mixture for the TPH assay requires an antioxidant as a preservative for  $\text{BH}_4$ . Avoidance of the site-specific Fenton Reaction by the addition of catalase ( $>4\text{mg/ml}$ ) were essential for the reaction to proceed quantitatively under aerobic conditions.

#### Availability of ferrous iron in the cell

The metabolism of iron may control 5-HT production by attenuating actual TPH activity in the cell interior.

In the previous section, the distinctive requirement that TPH has for iron was described in terms of the relatively rapid equilibrium of TPH with free  $\text{Fe}^{2+}$ ,  $8 < \text{Log } K_{\text{ML}} < 12$  (M and L denote  $\text{Fe}^{2+}$  and TPH, respectively). This feature was demonstrated by delivering ferrous iron to cells with hemin or via an iron shuttle with cell-permeable chelators. Hemin is  $\text{Fe}^{2+}$ -bound porphyrin, which integrates the iron catalytically through action of ferrochelatase (EC 4.99.1.1) and liberates  $\text{Fe}^{2+}$  by complex degradation catalyzed by heme-oxygenase (EC 1.14.99.3.) in the cell. When hemin was administered to cells in culture, it was taken up and the iron delivered, resulting in an elevation of the 'labile' or 'chelatable' iron pool (Rouault *et al.*, 1985). Hemin administration to RBL2H3 cells, a peripheral 5-HT-producing cell line, strongly elevated intracellular TPH activity in a steep

and concentration-dependent manner (Hasegawa *et al.*, 1999). The hemin-induced elevation of TPH activity was completely inhibited by administration of the cell-permeable chelator, salicylaldehyde isonicotinoyl hydrazone (SIH) or desferrioxamine (DFO), suggesting that hemin had liberated  $\text{Fe}^{2+}$  into the cytosolic pool of chelatable iron.  $\text{Fe}^{3+}$  complex with SIH also brought iron into the cell, resulting in only a two-fold elevation of TPH activity. The presumed equilibrium between free SIH and  $\text{SIH-Fe}^{3+}$  and also between free and  $\text{Fe}^{2+}$ -bound SIH both in and out of cells was established based on the fact that SIH was not metabolized but rather shuttled iron across the cell membrane (Ponka *et al.*, 1984). When administered to cells, free SIH suppressed TPH activity, as did DFO, and it may be that these compounds harbor chelated iron ions, as seen in Figure 5. TPH activity remained constant before and after treatment with hemin, SIH or DFO, as measured by a cell-free TPH assay, suggesting that the amount of TPH had not increased or decreased. The intracellular chelatable iron pool might be composed primarily of  $\text{Fe}^{2+}$ , but also contains multiple ligands, including peptides, nucleotides, and amino acids. This meant that a large proportion of TPH was in an inactive form due to a low concentration of available ferrous iron. In the erythroleukemia cell line K562, the chelatable iron pool was estimated *in situ* to be between  $2$  and  $5 \times 10^{-7}\text{M}$  using the fluorescent chelator calcein<sup>14</sup> (Breuer *et al.*, 1995). Furthermore, the concentration of chelatable iron in isolated hepatocytes under primary

**Figure 5** Chelatable iron pool. Extracellular administration (thick gray arrows) of (A) hemin, (B)  $\text{Fe}^{3+}$ -bound salicylaldehyde isonicotinoyl hydrazone (SIH), or the free cell-permeable chelators SIH or desferrioxamine (DFO). Internalized hemin is degraded to release  $\text{Fe}^{2+}$  irreversibly through the action of heme-oxygenase. The liberated  $\text{Fe}^{2+}$  pushes a series of reactions otherwise equilibrated along lines A1 and A2, resulting in a continuous increase in  $\text{Fe}^{2+}$ -TPH. Internalized  $\text{Fe}^{3+}$ -bound SIH (B) dissociates in part to liberate  $\text{Fe}^{3+}$ . This pushes iron ion pools along lines B2 up to B5 to increase free  $\text{Fe}^{2+}$ , also resulting in the increase in  $\text{Fe}^{2+}$ -TPH. However, the supply of dissociated  $\text{Fe}^{2+}$  is restrained, presumably due to an equilibrium between free and bound SIH as if it were a metal buffer. Addition of SIH (C) pushes a reaction to reserve  $\text{Fe}^{3+}$ -SIH (C1), consuming  $\text{Fe}^{3+}$  in the process, and this pulls  $\text{Fe}^{2+}$  through reactions along lines C2 down from C5, resulting in a decrease in  $\text{Fe}^{2+} = \text{TPH}$  (where '=' denotes liganding).  $\text{RH}_2$  represents the intracellular reducing pressure provided by energy metabolism. X and Y denote possible ligands with various affinities to iron ions.

culture was estimated to be  $5.4 \pm 1.3 \times 10^{-6}$  M using newly synthesized fluorescent chelators (Ma *et al.*, 2006).  $\text{Fe}^{3+}$  may be a minor component of the chelatable iron pool owing to the great capacity of cytosolic ferritin to bind under physiological conditions. Hence,  $\text{Fe}^{3+}$  might not be competitive with  $\text{Fe}^{2+}$  in the cell, although TPH is very sensitive to added or even ambient  $\text{Fe}^{3+}$  under cell-free experimental conditions *in vitro*. As mentioned in the above section on the 'Unique iron requirement of TPH', the apo-enzyme of TPH1 was fully active when the enzyme reaction was performed in  $8.7 \times 10^{-9}$  M  $\text{Fe}^{2+}$ -EGTA buffer; however, TPH was in fact in a 'hungry' state within the cell. In other words, the dissociable  $\text{Fe}^{2+}$  in living cells did not support the full potential activity of the enzyme, suggesting that the 'chelatable'  $\text{Fe}^{2+}$  pool that was available for TPH was smaller than that provided by the  $\text{Fe}^{2+}$ -EGTA buffer. Since the chelatable iron pool might be composed of ligands of varying affinity, and since measurement with a chelating probe is based on competition with intracellular ligands, estimated values might vary depending on the target cells and on the strength of the chelator. It is therefore considered that a large portion of the 'chelatable'  $\text{Fe}^{2+}$ , which was estimated using relatively strong chelators as the probe, might have not been available to TPH for ligand competition in the actual cell interior. A similar dissociation/association of iron ion was reported *in vivo* and *in vitro* with rat-liver PAH, a homologous pterin-dependent monooxygenase (Shiman and Jefferson, 1982). PAH activity was also manipulated in the liver by shuttling iron with transferrin under perfusion. As mentioned earlier, the stability of iron binding with PAH seems much higher than TPH1. PAH altered iron occupancy within 30 minutes, which was surprisingly rapid. As yet, TPH2 has not been compared with TPH1 with respect to its  $\text{Fe}^{2+}$ -hunger in the CNS. The size of the chelatable pool of  $\text{Fe}^{2+}$  or the concentration of  $\text{Fe}^{2+}$  available for TPH might be closely related to iron metabolism in the body as a whole. A latent iron deficiency in weaning rats gave rise to a 5-HT decrease in the CNS (Shukla *et al.*, 1989). Taken together, iron deficiency and 5-HT-related behavior appears to be an interesting subject for future exploration.

### Phosphorylation

Phosphorylation of TPH was studied in terms of its functional aspects with the use of brain TPH while identification of phosphorylation sites was mainly conducted on the basis of the amino acid sequence of TPH1.

Phosphorylation of TPH has drawn intense interest as a potential regulatory mechanism. In general, phosphorylation

is a post-translational modification which changes an enzyme's characteristics and can be reversed by dephosphorylation or by enzyme degradation. An approximately two-fold, *in vitro* activation with native brain TPH under  $\text{Ca}^{2+}$ -dependent phosphorylating conditions was reported in the late 1970s, and its responsible kinase was identified in 1983 to be  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase II (CaMK II; EC 2.7.11.17) (Yamauchi and Fujisawa, 1983). Phosphorylation of brain TPH *in vivo* by cAMP-dependent protein kinase (PKA; EC 2.7.11.11) was also suggested (Garber and Makman, 1987), and *in vitro* reconstitution of phosphorylation was carried out with brain extracts (Johansen *et al.*, 1995, 1996); however, enzyme activation *in vitro* was ambiguous. In both cases, CaMK II and PKA, and a third protein factor which could be present in incompletely purified enzyme preparations, were strongly implicated as mediators of the brain TPH activation. The enzyme activity of carefully purified native TPH was very similarly augmented by CaMK II or PKA, and each caused about a two-fold activation in the presence of 14-3-3 protein (Yamauchi *et al.*, 1981; Furukawa *et al.*, 1993; Winge *et al.*, 2008), suggesting that this protein was required for consolidating the activation. It was also suggested that phosphorylation with CaMK II attenuates proteolytic degradation in the presence of 14-3-3 protein (Murphy *et al.*, 2008; Winge *et al.*, 2008). The increase in catalytic activity with enzyme activation has been studied extensively with the brain enzyme, mainly consisting of TPH2. In contrast, phosphorylation of TPH1 triggered rapid degradation of the protein, as discussed in the next section (Iida *et al.*, 2002).

Phosphorylation sites on cDNA-deduced amino acid sequences of TPH1 and TPH2 are depicted in Figure 3. Phosphorylation at Ser58 in the regulatory domain of TPH1 has been well studied (for reviews, see Hufton *et al.*, 1995; Fitzpatrick, 1999; Mockus and Vrana, 1998), but most sequence related work on 'brain TPH' prior to 2003 would have involved TPH1. CaMK II was first discovered as a protein responsible for activation of brain TPH, as mentioned above. Its phosphorylation site has recently been identified to be Ser19 in the N-terminal region, a site which can be phosphorylated with PKA as well (Kuhn *et al.*, 2007; Murphy *et al.*, 2008; Winge *et al.*, 2008). The homologous downstream TPH2 region includes phosphorylation sequences similar to those of TPH1; however, to date, native TPH2 eludes phosphorylation of these sites.

### TPH protein turnover

The machinery of protein turnover is cell-type specific. TPH degradation is likely linked to protein phosphorylation.

Steady state levels of an enzyme are maintained as a counterbalance between its biosynthesis and degradation.

However, the enzyme level of TPH in a given cell or tissue generally does not correlate with its turnover rate. At any point in time, the amount measurable represents the steady state level; however, the turnover rate predicts how quickly the current level can increase or decrease on demand, usually as a response to stimulation (a good description can be found in Alberts *et al.*, 2002). A conventional but powerful method for estimating the turnover rate might be chasing the initial decrease rate after quickly stopping its biosynthesis. The decrease in the rate usually obeys first-order kinetics unless there is a particular underlying process which is driven by a limited number of high-affinity action sites. In this case, a linear decrease may be observed. In the case of the proteasome, which is a major and ubiquitous cytosolic apparatus, a virtually unlimited number of action sites may contribute. The observed initial rate of decrease would otherwise be undetectable due to compensation via biosynthesis. In a classic work by Meek and Neff (Meek and Neff, 1972), the half-life of the brainstem TPH was 2.5 days or longer as measured from the decline in the slope of TPH activity after administering a rat model a high dose of para-chlorophenylalanine (PCPA). A similar half-life was observed in MDMA-treated rat brain (single dose, 10 mg/kg, s.c.) using a metabolic assay which measured cortical 5-HTP accumulation after arresting AADC action with NSD1015 (Stone *et al.*, 1989b). When TPH levels in the brain are maintained under slow turnover conditions, a rapid stimulus response could be achieved by certain mechanisms other than quick degradation.

As for TPH1, its turnover rate was measured by administering cycloheximide (1 µg/ml) to cells in culture. The turnover rate expressed by the half-life ( $T_{1/2}$ ) was 15–40 minutes, depending on the cell conditions or on the characteristics of the 5-HT-producing cell lines; rodent mast cell lines RBL2H3, P-815 and FMA3.<sup>15</sup> The degradation was driven by the ubiquitin-proteasome pathway (Hasegawa *et al.*, 1995; Kojima *et al.*, 2000). It was demonstrated that phosphorylation of TPH functioned as a tag for TPH1 degradation by the ubiquitin-proteasome pathway (Iida *et al.*, 2002). The proteolytic degradation was ATP-dependent, and was prevented with proteasome-specific inhibitors such as lactacystin, as well as other proteasome inhibitors such as MG132 (carbobenzyl-Leu-Leu-Leu-H), but was not inhibited with E-64, a calcium-dependent inhibitor of calpains, or with non-lysosomal cysteine proteases also expressed ubiquitously in mammalian cells. The responsible protein kinase has not clearly been determined yet; *in vitro* phosphorylation by CaM/kinase II partially functioned to trigger MG-132-sensitive proteolysis, but PKA did not. TPH degradation by the proteasome through the phosphorylation-ubiquitination axis could be a major stimulus response

affecting the TPH level, at least in the mast cell system. The intracellular environment rather than the TPH protein itself might be responsible for the stimulus-response control of TPH turnover. The ubiquitin-proteasome system also determines properties of specifically differentiated cells. In this context, studies on regulation of TPH turnover should be restricted to particular cell systems operative in 5-HT-synthesizing cells.

## Tryptophan hydroxylase in behavioral neuroscience

### *Involvement of TPH in neural development*

The early expression of neurotransmitters and receptors in the developing brain has drawn attention to their potential contribution in modulating neuronal developmental processes. Monoamines are among the first neurotransmitters to develop during embryogenesis. Serotonergic neurons are generated on embryonic days 10 (E10) to E12 in the mouse (Levitt and Rakic, 1982). One day after their generation, raphe neurons can synthesize 5-HT.

The possible involvement of TPH at several stages of neural development was suggested from observations using a TPH blocker, *p*-chlorophenylalanine (PCPA). PCPA proved to specifically retard the onset of neuronal differentiation in brain regions known to contain 5-HT terminals or to have a high 5-HT content in the adult (5-HT target cells) in a study using long-survival 3H-thymidine autoradiography in rats (Lauder and Krebs, 1978). This finding indicates that TPH might have a role in neuronal differentiation, an early stage of neural development.

Neuronal differentiation is followed by the extension of axons and dendrites and the formation of the neural network. 5-HT is essential for 5-HT neurons to develop in an autocrine manner (Gaspar *et al.*, 2003), in addition to its action as a crucial neurotransmitter in various regions of the adult brain. Changes in the brain 5-HT content during development could disturb the development of 5-HT neurons. The consequence of TPH blockade on these developmental stages was further assessed using serotonergic RN46A cells under conditions where 5-HT is produced and released – that is, in the presence of BDNF and a high  $K^+$  (White *et al.*, 1994). Targeted deletions of molecules involved in the metabolism or transport of 5-HT in mice affected dendritic maturation during development (Gaspar *et al.*, 2003). However, gross abnormalities were not found in these mice. Since actin contributes to the fine-tuning of neural circuits during development (Luo, 2002), actin may affect maturation of 5-HT neurons. An 8-day blockade of TPH using PCPA resulted in a marked accumulation of F-actin just beneath the membranes in both the soma and the proximal and distal neuritic segments

(Nakamura *et al.*, 2006b), suggesting that TPH activity might affect maturation of 5-HT neurons via appropriate actin polymerization.

There is also evidence that TPH activity is required for the maturation of non-5-HT neurons. Since the cerebral cortex is widely innervated by 5-HT-containing axons originating from neurons in the raphe nuclei, an appropriate amount of 5-HT during development likely underlies the development of cortical neurons and dendritic arborization (Levitt *et al.*, 1997; Vitalis and Parnavelas, 2003). Major events in corticogenesis take place at the E12–17 stage of embryonic development in rats. E12–17 PCPA treatment altered the maturation of pyramidal neurons of layers III and V of the somatosensory cortex in rats, with these cells displaying reduced dendritic arborization and complexity (Vitalis *et al.*, 2007). In addition, the PCPA treatment transiently altered the incorporation in the cortical plate of interneurons derived from the caudal ganglionic eminence, and persistently affected the differentiation of a subpopulation expressing calretinin and/or cholecystokinin. Thus, TPH activity could contribute to multiple stages of neuronal development of multiple cell types.

### ***Effect of TPH on behavioral traits***

5-HT neurons project to several areas, such as the cortex and limbic system. These regions are responsible for the generation and expression of many brain functions such as sensorimotor functions and motivational and affective states. Thus, 5-HT is believed to be important through its neuromodulatory role in these regions. Accordingly, TPH, the rate-limiting enzyme in 5-HT biosynthesis, has the potential to affect multiple brain functions in the adult through regulation of brain 5-HT contents in these regions. For instance, repeated treatment with PCPA caused attenuation of prepulse inhibition (PPI) (Fletcher *et al.*, 2001; Prinssen *et al.*, 2002), the suppression of the startle response by a relatively weak earlier stimulus, which theoretically reflects sensorimotor gating (Braff and Geyer, 1990; Graham, 1975). As for aggression, PCPA increased social aggression in birds (Buchanan *et al.*, 1994) and induced muricidal aggression in male and female laboratory rats (Valzelli *et al.*, 1981), but inhibited fighting behavior of postpartum mice toward unfamiliar male intruder mice (Ieni and Thurmond, 1985).

In other studies, 5-HT was shown to be essential for 5-HT neurons to form in an autocrine manner during development (Gaspar *et al.*, 2003). The formation of proper neural circuits is sensitive to activities that occur during well-defined periods of postnatal development

(Berardi *et al.*, 2000). Proper TPH activity is likely required for the maturation of some brain functions within a narrow timeframe during development, and if this activity is compromised, it can adversely affect brain functions in the adult.

Pharmacological experiments were performed to define the sensitive period in the development of PPI. The blockade of TPH using PCPA from postnatal day 21 (P21) to P24, but not at earlier or later time-points, perturbed the PPI of adult mice. Reduced PPI in adulthood was also observed when PCPA was injected into rats during P21–P24. When the 5-HT precursor 5-HTP was given together with PCPA from P21 to P24, the attenuation of PPI was rescued in these rats. Therefore, in rodents, the sensitive period when proper TPH activity is required for PPI in adulthood proved to be from P21 to P24 (Nakamura *et al.*, 2006b). In addition, blockade of TPH during the embryonic period resulted in alterations in motor activity and learning in the adult. In rats, the prenatal PCPA increased activity in an open field in offspring treated on either gestational days (GD) 8–11 or 14–17. The highest levels of activity were noted in male and female offspring treated on GD 14–17. Similarly, the offspring treated on GD 14–17 showed a significant learning impairment in the Morris water maze (Vataeva *et al.*, 2007).

Since TPH2 mRNA is preferentially expressed in the brain (Walther *et al.*, 2003) and in peripheral myenteric neurons in the gut (Cote *et al.*, 2003), TPH2 might be involved in animal behavior by regulating 5-HT contents in the brain. A few reports support this notion. First, TPH2 mRNA in caudal dorsal raphe nucleus (DRN) was associated with lower anxiety-like behavior, whereas TPH2 mRNA in rostral dorsomedial DRN was associated with increased anxiety-like behavior (Hiroi *et al.*, 2006). Second, fluoxetine treatment for 4 and 8 weeks significantly increased basal TPH2 mRNA levels in the midbrain, an effect that was correlated with the appearance of antidepressant-like effects in the forced swim test, and a significant induction of TPH2 and 5-HT transporter mRNAs was detected in the midbrain of untreated rats 24 hours after the swim test (Shishkina *et al.*, 2007).

In contrast, TPH1 mRNA is mainly expressed in the pineal gland and the periphery (Walther *et al.*, 2003). However, the expression of TPH1 is up-regulated in the brain under some circumstances. Estrogen increased TPH1 mRNA expression in DRN of wild-type and ER- $\alpha$  knockout mice but not ER- $\beta$  knockouts, indicating that ER- $\beta$  is responsible for mediating estrogen-regulated TPH1 expression in the murine DRN (Gundlach *et al.*, 2005). Furthermore, a quantitative real-time PCR showed that TPH1 mRNA from male Wistar rats was up-regulated 2.5-fold in DRN by imposing daily restraint stress for

1 week. However, the expression of TPH2 was not affected by the stress in DRN (Abumaria *et al.*, 2008). These data raise the attractive hypothesis that TPH1 in serotonergic neurons of the DRN might be involved in stress-induced psychopathologies.

### *TPH in psychiatric conditions*

The human TPH1 gene represents a candidate for genes involved in psychiatric conditions. The polymorphism A779C in intron 7 of TPH1 has been reported to be associated with alcoholic offenders (Nielsen *et al.*, 1998). In addition, the association of TPH1 with suicidal behavior has been well studied. As one example, A779C has been reported to be associated with suicidal behavior in depressed patients (Mann *et al.*, 1997). Another study reported that the association between TPH1 and suicidal behavior is stronger with violent suicidal behavior (Abbar *et al.*, 2001). Several recent meta-analyses have concluded that there is an association between A218C and a history of suicide attempts in Caucasians (Rujescu *et al.*, 2003; Bellivier *et al.*, 2004). Suicidal behavior has been implicated in the relationship between TPH1 and mood disorder. Bellivier and colleagues (1998) initially reported an association between TPH1 and bipolar disorder. However, in their study, the frequency of the allele was significantly associated with a history of suicidal behavior in bipolar subjects. Therefore, the reported association with bipolar disorder might be linked to suicidal behavior. Four subsequent studies found no association between TPH1 and bipolar disorder, and three of these studies, in which the population of bipolar patients was stratified according to their history of suicidal behavior, found no association with suicidal behavior in bipolar subjects (Furlong *et al.*, 1998; Kirov *et al.*, 1999; McQuillin *et al.*, 1999; Tsai *et al.*, 1999). Likewise, Zaboli *et al.* (2006) proposed that TPH1 is associated with borderline personality disorder in suicidal women. Collectively, TPH1 may be involved in susceptibility to suicidal behavior in some populations. Courtet *et al.* (2005) suggested that TPH may be a quantitative risk factor where the more pronounced the serotonergic dysfunction, the higher the levels of anger and the more severe the suicidal act (involving lethality, violence, repeated suicide attempts, completed suicide).

As for TPH2, there are reports suggesting an association between TPH2 and mood disorders. In addition, TPH2 gene variation is suggested to influence personality traits and disorders related to emotional dysregulation (Gutknecht *et al.*, 2007; Reuter *et al.*, 2007). Further studies will confirm the involvement of TPH2 in specific psychiatric conditions.

### Notes

1. The responsible enzyme, PCD/DCoH, is a bifunctional protein which is not likely to be expressed in the CNS (Davis and Kaufman, 1989). This intermediate dehydrates spontaneously at a neutral pH.
2. Tryptophan was formerly a popular 'home remedy'. Since very small amounts of impurities were formed during its mass production, the supplement was judged to be neurotoxic and disappeared from the market. The impurity might have been generated during the drying process under air.
3. The major reason for the instability seems to be related to the nature of ferrous iron, whose behavior is difficult to control under aerobic conditions *in vitro*, and is dissociable from the enzyme. See the section on 'Iron requirement'.
4. Sepiapterin administration is so far the best method for increasing the BH<sub>4</sub> concentration inside many types of the cells, including RBL2H3, PC12 and primary cultures of hepatocytes. Sepiapterin is incorporated by a transporter(s) and converted to BH<sub>4</sub> by the salvage pathway, while BH<sub>4</sub> is rejected by these cells by incorporation into the cytosolic compartment followed by immediate oxidation and release (Hasegawa *et al.*, 2005; Sawabe *et al.*, 2008).
5. With purified preparations, the K<sub>m</sub> values of DHPR, as determined by the cytochrome-c method, were reported to be 1.5 and 74 μM for NADH and NDDPH (V<sub>max</sub>, 8.5 μmol/min per mg), respectively. Enzymic data of DHPR from the livers of sheep, cows, and humans were concisely summarized in *Methods in Enzymology*, Vol. 142 (1987). As an indication of available reduced pyridine nucleotides, the ratios of reduced and oxidized forms (NAD<sup>+</sup>/NADH and NADP<sup>+</sup>/NADPH) within the cytosolic compartment of liver cells were 1.16 and 0.014, respectively (Krebs and Veech, 1969).
6. Folic acid is a 'conjugated pterin' and biopterin is an 'unconjugated pterin'. Owing to the enormous role of DHFR in reducing 7,8-dihydrofolate to tetrahydrofolate, which functions as the essential carrier of 1-carbon in DNA synthesis, its inhibitors such as methotrexate MTX have been employed as classic anti-tumor drugs. In animal experiments, tissue BH<sub>4</sub> levels were significantly decreased or those of BH<sub>2</sub> were elevated by administration of MTX (Sawabe *et al.*, 2004).
7. Patients with a hereditary DHPR deficiency secrete large amounts of 7,8-BH<sub>2</sub> in the urine, but suffer from a severe deficiency of its reduced form (BH<sub>4</sub>) which supports monoamine biosynthesis.

8. Circulating BH<sub>2</sub> is quickly taken up by many cells, including erythrocytes, where it is reduced back to BH<sub>4</sub> (Hasegawa *et al.*, 2005; Sawabe *et al.*, 2008). No large amounts of BH<sub>2</sub> appear in the urine; BH<sub>4</sub>, the fully reduced form, appears instead.
9. Since there is no major degradation pathway of BH<sub>4</sub> as far as we know, renal excretion essentially reflects the amount of BH<sub>4</sub> biosynthesis. Daily renal excretion of a healthy rat was around 0.4 mg/kg (adult male, SD, unpublished). Healthy daily excretion of BH<sub>4</sub> into the human adult urine amounts to roughly 20 mg a day. The daily dose required to treat a BH<sub>4</sub> deficiency (5–20 mg/kg per day) is 15- to 60-fold greater than the putative amount synthesized in the body.
10. The activation procedure had the great advantage of retrieving the full potential activity of the enzyme. However, the activation required strictly anaerobic conditions, and this was achieved in a Thunberg tube connected to a vacuum line switchable to inert gas (argon or nitrogen). In addition, the enzyme reaction had to be performed within a short period to assess the linear progress against inactivation under air. These could be the reasons why the method did not become widely used.
11. In the reaction for catalase scavenging of H<sub>2</sub>O<sub>2</sub>, the reaction rate is determined by the rate of collision between the enzyme and H<sub>2</sub>O<sub>2</sub>, similar to the non-enzymic chemical reaction. H<sub>2</sub>O<sub>2</sub> is generated by an oxygen molecule coupled with the reaction, Fe<sup>2+</sup> to Fe<sup>3+</sup> and/or XH<sub>2</sub> to X, where XH<sub>2</sub> stands for the reducing reagent. The H<sub>2</sub>O<sub>2</sub> concentration is quite low, and in this case, the catalase concentration should be high enough for effective scavenging. Note that a 'high concentration' of catalase, such as 1 mg/ml, is merely a catalase-subunit concentration of 17 μM; not a very high concentration. With many published methods, a catalase concentration below 2 mg/ml may not be sufficient for this purpose, depending on how urgently the scavenging is required.
12. Under typical assay conditions, the TPH concentration (0.2 μg pure enzyme in a 150-μL reaction mixture) was calculated to contain around  $2.67 \times 10^{-8}$  mol/l of TPH molecules (subunit mw: 53,000). If 5 percent of subunits carried bound Fe<sup>3+</sup>, the iron might have been converted by DTT to  $1.33 \times 10^{-9}$  M Fe<sup>2+</sup>, which was close to the Fe<sup>2+</sup> concentration in the  $8.7 \times 10^{-9}$  M Fe<sup>2+</sup>-EGTA buffer mentioned in the text. As long as the bound iron was dissociable, this concentration was high enough for the enzyme to exert virtually full activity.
13. The stability constants of representative chelators EGTA and EDTA with ferrous iron Fe<sup>2+</sup> were

found to be 11.9 and 14.3 (log K<sub>ML</sub>), respectively, in log expression. An Fe<sup>2+</sup>-EGTA buffer, 100 μM Fe(NH<sub>4</sub>)<sub>2</sub>(SO<sub>4</sub>)<sub>2</sub>, 1 mM EGTA, might have yielded  $8.7 \times 10^{-9}$  M Fe<sup>2+</sup> aquo ions at pH 6.7, or by replacing EGTA with EDTA,  $1.8 \times 10^{-12}$  M Fe<sup>2+</sup>. Since the stability constants of these chelators to Fe<sup>3+</sup> (log K<sub>ML</sub> for Fe<sup>3+</sup>) are much higher, 20.5 and 25.1, respectively, the free Fe<sup>3+</sup> ion was selectively masked off the system (Hasegawa and Ichiyama, 1986, 2005). The ion concentration was calculated using the PC application 'EQCAL' (Backman, 1988) based on an algorithm developed by Eriksson (1979).

14. Calcein, the fluorescent probe employed in this estimation, is a strong ligand of iron ion, comparable with EDTA (Breuer *et al.*, 1995). The stability constants (Log K<sub>ML</sub>) of EDTA to Fe<sup>3+</sup> and Fe<sup>2+</sup> are 25.1 and 14.33, respectively. Those of EGTA are 20.5 and 11.92, respectively. As an Fe<sup>2+</sup> ligand, EGTA was not competitive with TPH1, but at the same time, EGTA could remove the bound Fe<sup>3+</sup> from inactive TPH1 (Hasegawa and Ichiyama, 2005).
15. These mast cells respond to a stem cell factor, SCF; a ligand for c-kit, while P-815 and FMA3 carry a mutation for constitutive activation at the c-kit, KIT ligand receptor tyrosine kinase (Tsujimura *et al.*, 1996). P-815 and FMA3 continuously express high levels of TPH1. RBL2H3, a rat basophilic leukemia derived cell line, expresses relatively low levels of TPH1 while its expression is controlled by antigen-IgE stimulation (Hasegawa *et al.*, 1996).

**Abstract:** The enzymatic degradation of serotonin (5-hydroxytryptamine, 5-HT) is mainly served by monoamine oxidase (MAO), a mitochondrial-bound enzyme requiring flavin adenine dinucleotide as a cofactor. MAO catalyzes the oxidative deamination of 5-HT by converting it into 5-hydroxy-3-indolacetaldehyde (5-HIAL), which is further processed into 5-hydroxy-3-indolacetic acid (5-HIAA) by aldehyde dehydrogenase. MAO also serves the degradation of other monoamine neurotransmitters, such as norepinephrine, dopamine and trace amines. Two MAO isoenzymes, named A and B, have been identified, which differ in genetic bases, transcriptional regulation, substrate preference, inhibitor affinity and regional distribution. Although MAO A exhibits the highest preference for 5-HT and catalyzes its metabolism under physiological conditions, MAO B is the only isoenzyme that has been identified in 5-HTergic neurons. This chapter reviews the evidence on the biochemistry, genetics and neurobiology of MAOs, in relationship to their functions in the regulation of 5-HTergic neurotransmission, as assessed by studies on the outcomes of their pharmacological and genetic inactivation.

**Keywords:** monoamine oxidase, 5-HT, catabolism.

## Introduction: pathways of serotonin degradation

One of the key functional premises for the proper regulation of serotonin (5-hydroxytryptamine, 5-HT) neurotransmission is its rapid reuptake and enzymatic degradation. The main pathway of 5-HT metabolism, in the brain and peripheral tissues, is mediated by the enzyme monoamine oxidase (MAO), and consists of its deaminative oxidation to 5-hydroxy-3-indolacetaldehyde (5-HIAL).

This compound is further processed by an NAD<sup>+</sup>-dependent aldehyde dehydrogenase (ALDH) into 5-hydroxy-3-indolacetic acid (5-HIAA). Small amounts of 5-HIAL have been shown to be converted into 5-hydroxytryptophol (5-HTOL) by either an NADH-dependent aldehyde reductase (ALR) or an NADPH-dependent alcohol-dehydrogenase (ADH) (Feldstein and Williamson, 1968; Consalvi *et al.*, 1986; Svensson *et al.*, 1999) (Figure 1). While the physiological brain concentration of 5-HTOL is only 1–5% of the 5-HIAA levels (Beck *et al.*, 1984), intake of ethanol has been shown to produce a dramatic increase of 5-HTOL production (Helander *et al.*, 1993),

probably as a result of competitive inhibition of ALDH, as well as an increased NADH/NAD ratio, which enhances ADH activity (Davis *et al.*, 1967; Lahti and Majchrowicz, 1974; Beck *et al.*, 1982). Interestingly, this observation has led some authors to propose 5-HTOL/5-HIAA ratio as a sensitive marker of recent alcohol drinking (Voltaire *et al.*, 1992; Helander *et al.*, 1996).

5-HIAA is rapidly eliminated by diffusion, transported into the bloodstream and excreted through the kidneys (Udenfriend *et al.*, 1956) through a combined mechanism of glomerular filtration and active tubular excretion (Despopoulos and Weissbach, 1957). Urinary 5-HIAA concentrations are considered a dependable index of 5-HT peripheral concentrations (or MAO activity), and are commonly used to monitor the effects of MAO pharmacological inhibition or to screen for carcinoid syndrome, a disorder characterized by increased 5-HT release by some gastrointestinal endocrine tumors.

Similar considerations have also prompted researchers to use 5-HIAA concentrations in the cerebrospinal fluid (CSF) as an indicator of 5-HT turnover (Jimerson, 1985). Low CSF 5-HIAA levels have been repeatedly associated with certain psychiatric conditions, such as impulsivity, attempted suicide, antisocial behavior (Asberg *et al.*, 1976; van Praag, 1983; Mehlman *et al.*, 1994; Virkkunen *et al.*, 1995).

**Figure 1** Metabolic pathways of 5-HT. MAO catalyzes the conversion of 5-HT into 5-hydroxy-3-indolacetaldehyde (5-HIAL), which is then further degraded to 5-hydroxy-3-indolacetic acid (5-HIAA). Alternatively, 5-HIAL can be converted into 5-hydroxytryptophol (5-HTOL) by aldehyde reductase (ALDR) or alcohol dehydrogenase (ADH). 5-HT can also be conjugated to sulfate or glucuronyl (not shown) groups by transferases. In the pineal gland, 5-HT is converted to *N*-acetylserotonin (NAS) by *N*-acetyl transferase. NAS is then transformed into melatonin by hydroxyindole-*O*-methyltransferase. For further details, see text.

Besides MAO-mediated degradation, 5-HT can undergo other secondary bioconversion pathways, such as conjugation to sulfate by means of a sulfotransferase (Hammond *et al.*, 1981; Hidaka *et al.*, 1969; Elchisak, 1983; Stuart *et al.*, 2003) (Figure 1), or glucuronylation by means of a glucuronyl-transferase (Tyce *et al.*, 1968). 5-HT is also converted to melatonin by acetylation (catalyzed by *N*-acetyl transferase) and subsequent methylation by hydroxyindole-*O*-methyltransferase (Nambodiri *et al.*, 1987; Sugden *et al.*, 1987) (Figure 1). This pathway has been shown to occur mainly in the pineal gland, although it is present also in other tissues, such as retina, gastrointestinal tract and thyroid (Kvetnoy, 1999). Other metabolites of 5-HT, such as 5-hydroxyindole thiazoladine carboxylic acid (5-HITCA), have been recently identified (Squires *et al.*, 2006). Nevertheless, these secondary pathways seem to play only a minor role in the metabolism and regulation of 5-HT.

In consideration of the predominant role of MAO in 5-HT metabolism, this chapter will provide a synoptic

view on the state of the art of MAO biochemistry and genetics, and will illustrate the available evidence on the key functional role played by this enzyme in the regulation of 5-HT signaling and its functional correlates in behavioral organization.

### MAO: general characteristics

MAO (amine: oxygen oxidoreductase (deaminating) (flavin-containing); MAO; E.C. 1.4.3.4) is a mitochondrial-bound flavoprotein, catalyzing the oxidative deamination of 5-HT and other monoamine neurotransmitters, such as norepinephrine, dopamine, epinephrine and trace amines ( $\beta$ -phenylethylamine, tryptamine, tyramine, etc.). Furthermore, MAO also serves a cytoprotective role by degrading exogenous amines, which exert their toxicity by affecting cardiovascular and endocrine homeostasis.

The enzyme was first isolated from extracts of rabbit liver in 1928, by Mary Hare, who named it tyramine

oxidase in reference to its ability to catalyze the conversion of tyramine into *p*-hydroxyphenylacetic acid (Hare, 1928). The current nomenclature was actually proposed 10 years later, following the identification of the full spectrum of the monoaminergic substrates served by the enzyme (Zeller, 1938).

The chemical reaction catalyzed by MAO requires flavin adenine dinucleotide (FAD) as a redox cofactor is performed on monoamine substrates in their neutral, deprotonated forms (Edmondson *et al.*, 1993; Miller and Edmondson, 1999) and consists of the conversion of monoamines into the corresponding aldehydes.

Research has shown that the catalytic action of MAO starts with the cleavage of the C<sub>α</sub>-H bond of the deprotonated form of monoamine substrates (Edmondson *et al.*, 1993; Miller and Edmondson, 1999). Specifically, FAD accepts two hydrogen atoms and is reduced to FADH<sub>2</sub>, while the amine is converted into the correspondent imine:

Although the details of this process are still unclear, several theories have been proposed to explain them, including: an addition-elimination mechanism (Kim *et al.*, 1993) with formation of flavin-amine adducts; a proton abstraction reaction with a carbanion intermediate (Walker and Edmondson, 1994); and the formation of amine radical cations by single electron transfer to FAD (Silverman and Hawe, 1995). This last reaction, however, is considered unlikely, as it is not favored thermodynamically (Edmondson *et al.*, 2007).

In most cases, the second step of MAO reaction consists of the re-oxidization of FADH<sub>2</sub>, with the conversion of oxygen into hydrogen peroxide:

Finally, the imine is hydrolyzed into the corresponding aldehyde and ammonia:

As mentioned above, aldehydes are mainly oxidized into acids by ALDH, but can also be converted into alcohols or glycols by ADH or ALR. A typical example of this latter mechanism is the peripheral metabolism of norepinephrine, which is converted into 3,4-dihydroxyphenylglycol (DHPG) and then further degraded by COMT into 3-methoxy-4-hydroxyphenylglycol (MHPG).

The byproducts of MAO-catalyzed reactions include potentially neurotoxic species, such as hydrogen peroxide

and ammonia. In particular, hydrogen peroxide can trigger the production of reactive oxygen species (ROS) and induce mitochondrial damage and neuronal apoptosis. The oxidative stress induced by MAO activation may be critical in the pathogenetic mechanisms of several disorders in which this enzyme has been implicated, such as Parkinson's disease or depression (Bortolato *et al.*, 2008).

## MAO isoenzymes

In 1968, two separate MAO isoenzymes – respectively named A and B – were postulated based on the differential selectivity MAO inhibitors. MAO A was defined as the isoenzyme inhibited by low doses of clorgyline, while MAO B was blocked by nanomolar concentrations of (R)-deprenyl (Johnston, 1968; Squires, 1968; Knoll and Magyar, 1972). This distinction was also paralleled by findings on the spectrum of affinity for different monoamine substrates. Although the two isoenzymes do not have absolute substrate specificity, 5-HT is mainly degraded by MAO A, with affinity 120-fold higher than MAO B. MAO A also prefers norepinephrine, while MAO B is the main enzyme for β-phenylethylamine catabolism.

The metabolism of dopamine and tyramine is generally served by both isoenzymes, albeit with considerable differences across species. For instance, while the metabolism of dopamine is mainly served by glial MAO B in humans, primates and other mammals (Garrick and Murphy, 1980), it is only metabolized by MAO A under basal conditions and by both isoenzymes at high concentrations in mice (Cases *et al.*, 1995; Fornai *et al.*, 1999). Finally, dopamine is always metabolized by MAO A in rats, regardless of the concentrations (Fornai *et al.*, 1999).

The different molecular nature of the two MAO isoenzymes was unequivocally demonstrated in 1988, with the cloning of the cDNA of *Maoa* and *Maob* genes from humans (Bach *et al.*, 1988; Hsu *et al.*, 1988). The comparison of the deduced amino acid sequences of the two isoenzymes indicates that they share 70 percent sequence identity, consist of 527 and 520 amino acids, and have molecular weights of 59.7 kDa and 58.8 kDa, respectively. The cloning of bovine and rat MAO A and MAO B (Ito *et al.*, 1988; Powell *et al.*, 1989; Kuwahara *et al.*, 1990; Kwan and Abell, 1992) revealed high levels of sequence identity across different mammalian species.

The availability of MAO cDNA clones made possible the isolation and characterization of the human *Maoa* (Chen *et al.*, 1991; Grimsby *et al.*, 1991; Kwan *et al.*, 1992) and *Maob* (Grimsby *et al.*, 1991; Kwan *et al.*, 1992) gene structure and localization.

Both genes are located on the X chromosome (Xp11.23 in humans), in opposite directions with tail-to-tail orientation (Lan *et al.*, 1989a; Levy *et al.*, 1989; Ozelius *et al.*, 1988), and are composed of 15 exons and span over 60 kb. The observation that MAO A and MAO B share identical exon–intron organization suggests their origin from a common ancestral gene (Grimsby *et al.*, 1991). The occurrence of two MAO isoenzymes can be traced back to the anuran amphibians (Kobayashi *et al.*, 1981): in these vertebrates, MAO A is notably predominant in the tadpole stage, while MAO B expression increases through metamorphosis (Nicotra and Senatori, 1988). In consideration of the different roles of various monoamines in the regulation of blood pressure and heart functioning, the development of target-specific MAO isoenzymes was probably instrumental to the new challenges posed by terrestrial life to the cardiovascular system, in parallel to other adaptive neuroendocrine mechanisms (Takei *et al.*, 2007).

The availability of MAO A and B clones allowed the selective transfection of their cDNAs in mammalian cells, leading to the discovery that the expressed enzymes were catalytically active and displayed substrate and inhibitor specificities similar to those of the endogenous enzymes (Lan *et al.*, 1989b) (Figure 2). This important finding demonstrated that only one polypeptide was required for the catalytically active form of MAO A or MAO B.

Expression of site-directed MAO mutants in COS cells confirmed that covalent attachment of FAD to cystein residues in both isoenzymes (Cys-406 in MAO A and Cys-397 in MAO B) (Wu *et al.*, 1993) is critical for their enzymatic activity. Additional site-directed mutagenesis

studies determined that the cysteine residues that play a critical role for enzymatic activity are in position 374 for MAO A and positions 156 and 365 for MAO B (Wu *et al.*, 1993). We also demonstrated that substrate and inhibitor specificities in human MAO isoenzymes are conferred by an isoleucine residue in position 335 and a tyrosine residue in position 326 in human MAO A and B, respectively (Geha *et al.*, 2001).

Studies on MAO A/B chimeric enzymes ascertained that the difference in substrate preference and inhibitor specificity was conferred by an internal segment between amino acids 161 and 375 for MAO A and amino acids 152 and 366 for MAO B, but not by the N- or C-terminal regions (Gottowik *et al.*, 1993; Chen *et al.*, 1996; Shih *et al.*, 1998; Geha *et al.*, 2000). Furthermore, it was discovered that FAD was covalently bound – through a thioester linkage – to the cystein residue of a pentapeptidic sequence (Ser–Gly–Gly–Cys–Tyr) located between aa 403 and 407 in MAO A and aa 394 and 398 in MAO B (Kearney *et al.*, 1971; Bach *et al.*, 1988; Hsu *et al.*, 1988).

The determination of MAO 3D structure with X-crystallographic studies (Binda *et al.*, 2002, 2003; Ma *et al.*, 2004; De Colibus *et al.*, 2005) revealed that human MAO A displays a monomeric organization (Andrés *et al.*, 2004; De Colibus *et al.*, 2005), with a monoamine-binding cavity size of 550 Å<sup>3</sup> and a FAD site opposite to the entrance. Two tyrosine residues are predicted to facilitate substrate placement for the catalytic activity (Edmondson *et al.*, 2007). In contrast, human MAO B crystallizes as a dimer, and displays two cavities separated by a isoleucine gate, which can exist in either an open or a closed

**Figure 2** Inhibition of MAO A and MAO B expressed in COS cells by deprenyl and clorgyline. MAO A and MAO B activity was assessed using 5-HT and  $\beta$ -phenylethylamine, respectively, as substrates in the presence of various concentrations of inhibitors. Modified from Lan *et al.* (1989a).

conformation depending on the size of the substrate (Hubalek *et al.*, 2005). The FAD binding site is similar to that identified for MAO A (Edmondson *et al.*, 2007). Overall, these results are in substantial agreement with earlier findings of mutagenesis studies (Geha *et al.*, 2001, 2002).

### Transcription and translation of MAO

Over the past 20 years, our group has afforded significant contributions in the understanding of the transcriptional regulation of *Maoa* and *Maob* genes. While the detailed illustration of these findings is beyond the scope of the present chapter (see Chen, 2004; Shih and Chen, 2004), it is worth noting that the promoters of both genes, as well as their mechanisms of activation and repression, are remarkably different (Shih *et al.*, 1994). Human MAO B expression, for example, is activated by protein kinase C and MAPK signaling transduction pathways (Wong *et al.*, 2002), while it is decreased by methylation (Wong *et al.*, 2003). A key role in the regulation of the expression of both genes is played by the family of the transcription factor Sp1 (Zhu *et al.*, 1994; Wong *et al.*, 2001). We also identified R1, a novel repressor of *Maoa* gene expression (Chen *et al.*, 2005). Notably, both R1 and Sp1 activities are modulated by glucocorticoids and androgens (Ou *et al.*, 2006).

Several studies have indicated that the transcriptional activity of human *Maoa* gene may be affected by different variants of an extensive repeat structure located in the promoter, 1.2kb upstream of the MAO A coding sequence. The functional significance of this motif and its role in behavioral regulation will be discussed below.

Like other mitochondrial proteins, MAOs are synthesized by free ribosomes in the cytosol (Sagara and Ito, 1982). Neither isoenzyme, however, features the signal sequence in the N-terminal domain typical of mitochondrial protein precursors (Roise and Schatz, 1988). Indeed, it has been established that the C-terminus of MAO B contains the sequence for targeting the mitochondrial outer membrane (Mitoma and Ito, 1992) and attaching to it (Rebrin *et al.*, 2001). Insertion of both MAO A and MAO B into the mitochondrial outer membrane requires ubiquitin and ATP (Zhuang *et al.*, 1988, 1992; Zhuang and McCauley, 1989). The specific mechanism of incorporation into the outer mitochondrial membrane, however, is still poorly understood.

### Localization and distribution of MAO

The localization of both MAO A and MAO B in the central nervous system and across different peripheral tissues

has been studied in different species using numerous complementary approaches, such as the use of enzyme inhibitors, immunohistochemistry, autoradiography and *in situ* hybridization.

As MAO is bound to the outer mitochondrial membrane (Greenawalt and Schnaitman, 1970), it is present in most cells, with the obvious exception of red blood cells. Nevertheless, the pattern of distribution of MAO A and MAO B is remarkably distinct.

In humans, MAO A is highly expressed in the liver, lung, placenta and small intestine, while its lowest levels are found in the spleen and brain microvessels. Furthermore, MAO A is not found in platelets and lymphocytes (Bond and Cundall, 1977; Donnelly and Murphy, 1977). In contrast, the levels of MAO B expression are highest in the small intestine, liver and brain, and poor in the pancreas, spleen, lung, and skin fibroblasts. Interestingly, this isoenzyme is absent in placental tissue (Dahlstroem and Fuxe, 1964; Grimsby *et al.*, 1990).

Although the brain exhibits high concentrations of MAO A and MAO B, their regional and cell-specific localization is also strikingly different. Specifically, MAO A is predominantly found in catecholaminergic neurons (and in particular in the locus coeruleus, nucleus accumbens, hypothalamus and mammillary complex). In contrast, MAO B is found in 5-HTergic neurons, but also in histaminergic cells and in astrocytes (Westlund *et al.*, 1988; Saura *et al.*, 1994; Luque *et al.*, 1995; Jahng *et al.*, 1997).

The functional significance of the pattern of distribution of MAO isoenzymes in the brain is still partially unclear, in consideration of their substrate specificity. For instance, the localization of MAO B in the 5-HTergic neurons is seemingly at variance with rich evidence showing that 5-HT is preferentially degraded by MAO A (see above) and that inactivation of MAO A, but not MAO B, results in 5-HT level enhancement (Mousseau and Greenshaw, 1989; Cases *et al.*, 1995; Grimsby *et al.*, 1997). Indeed, MAO B is the only isoenzyme identified in the cell bodies and dendrites of 5-HTergic neurons in the raphe nuclei (Levitt *et al.*, 1982). Nevertheless, MAO A mRNA has been repeatedly observed in these cells (Luque *et al.*, 1995; Jahng *et al.*, 1997; Filipenko *et al.*, 2002).

An intriguing hypothesis that may account for these apparent discrepancies is that, in 5-HTergic neurons, MAO A protein may actually be synthesized in the cell body (or axon hillock), anchored to select mitochondria and transported by microtubules or other mechanisms to the axon terminals located in different brain areas, such as the cortex, amygdala, hippocampus, etc. (Jacobs and Azmitia, 1992) (Figure 3). This possibility is indirectly supported by the finding that MAO B expression is abundant in the mitochondria located in the somata of

**Figure 3** Hypothetical compartmentalization of MAO A and MAO B in 5-HTergic neurons. We propose that the localization of MAO B (represented as a semi-oval shape in the left box) is limited to the mitochondria of the cell body and dendrites of the 5-HTergic neuron. Conversely, MAO A (schematized as an elliptic shape on the mitochondria in the right box) may be mainly distributed in the synaptic terminals, where it would degrade the 5-HT after its reuptake operated by 5-HT transporter (5-HTT). For more details, see text.

5-HTergic neurons, but completely absent from the mitochondria in their axon terminals (Arai *et al.*, 2002). The differential subcellular location of MAO B-containing and MAO B-free mitochondria may reflect their different interactions with kinesins, the motor proteins in charge of anterograde mitochondrial transport through microtubules (Goldstein, 2001; Hollenbeck and Saxton, 2005).

Interestingly, the identification of MAO A-containing mitochondria in axon terminals (Westlund *et al.*, 1993) suggests that they are efficiently transported to this compartment by microtubules. Further investigations regarding the possible interactions between MAO isoenzymes and kinesin receptors are warranted to understand the molecular mechanisms underpinning these differences.

The proposed compartmentalization of MAO isoenzymes in 5-HTergic neurons might respond to specific physiological requirements for the proper processing of 5-HT synthesis, vesicular uptake and metabolism. Indeed, several lines of evidence point to an independent regulation of formation and degradation of 5-HT in the cell body and axon terminals of 5-HTergic neurons (Neckers, 1982; Daszuta *et al.*, 1984a, 1984b).

Although 5-HT synthesis can occur in the axon terminal, it is physiologically more abundant in the cell body (Daszuta *et al.*, 1984a; Pivac *et al.*, 2003). Thus, in consideration of the high affinity of MAO A for 5-HT, the localization of this enzyme in the soma may arguably compete with the gradient-based mechanism of 5-HT vesicular uptake. On the other hand, the presence of MAO A in the synaptic terminal may facilitate the degradation of 5-HT after its reuptake mediated by 5-HT transporter (5-HTT). Conversely, the presence of MAO B in the body of 5-HTergic neurons may prevent the uptake of wrong amine neurotransmitters in the vesicles. Furthermore, this isoenzyme may catalyze the degradation of trace amines such as  $\beta$ -phenylethylamine and tryptamine, which have

been suggested to deplete the content of 5-HT in the vesicles by virtue of an amphetamine-like mechanism (Burchett and Hicks, 2006).

### Role of MAO in behavioral regulation: pharmacological inhibition

The development and design of MAO inhibitors was originally prompted by the fortuitous discovery that iproniazid – a derivative of isoniazid originally designed to improve the antitubercular properties of this agent – exerted remarkable mood-enhancing properties (Fox and Gibas, 1953). Capitalizing on the finding that this compound was also a potent, irreversible MAO blocker (Zeller and Barsky, 1952), several researchers postulated a link between MAO, its substrates and mood control. This theory was substantiated by the antidepressant activity of novel irreversible MAO inhibitors, such as nialamide (Rowe *et al.*, 1959) and phenelzine (Saunders *et al.*, 1959). The widespread success and use of MAO inhibitors in clinical practice was paralleled by multiple reports of their side effects. In particular, serious concerns stemmed from the description of the ‘cheese reaction’, an often lethal hypertensive crisis due to the absorption of tyramine or other sympathomimetic amines contained in fermented food, such as cheese, wine, etc. (Anderson *et al.*, 1993). Due to the inactivation of intestinal MAO, high concentrations of these dietary amines could circulate in the bloodstream and cause excessive sympathetic activation and systemic vasoconstriction.

The hazards of MAO inhibitors propelled the development of novel categories of antidepressant drugs, such as tricyclics and selective serotonin reuptake inhibitors (SSRIs), leading to the characterization of selective antidepressant agents with better tolerability which gradually

supplanted MAO inhibitors. Only the recent production of reversible MAO A inhibitors (which can be replaced by dietary amines and do not induce the cheese effect) has rekindled interest for this category of drugs.

There is a general consensus that the antidepressant properties of MAO inhibitors are actually to be ascribed to the blockade of MAO A, particularly in view of its action on 5-HT metabolism and the consequent ability to counter the decline in 5-HT observed in depression. Indeed, MAO A inhibition has been shown to increase 5-HT concentrations in the synaptic cleft (Sharp *et al.*, 1997) and to affect firing of 5-HTergic neurons in the dorsal raphe nucleus (Aghajanian *et al.*, 1970; Blier and de Montigny, 1985), and these effects have been suggested to underpin the antidepressant effects of MAO inhibitors. The link between the antidepressant effects of MAO inhibitors and 5-HTergic system is also supported by several lines of evidence, showing that the neurochemical, neurophysiological and behavioral outcomes of acute MAO blockade are reversed by 5-HT<sub>1A</sub> receptor antagonists (Verge *et al.*, 1986; Sotelo *et al.*, 1990; Sharp *et al.*, 1997; Moser and Sanger, 1999). Nonetheless, it is possible that the actions of MAO inhibitors on norepinephrine (and, to a more limited extent, dopamine) signaling may contribute to their high efficacy in depression-related symptoms which tend to respond poorly to SSRIs (Amsterdam and Shults, 2005), such as dysthymia (Vallejo *et al.*, 1987), bulimia and hypersomnolence (Thase *et al.*, 1992; Carruba *et al.*, 2001).

MAO inhibitors are also indicated for a number of anxiety-spectrum disorders which have been shown to depend on alterations of 5-HTergic signaling, including social phobia, agoraphobia and panic disorder, post-traumatic stress disorder (Cyr and Farrar, 2000) and obsessive-compulsive disorder (OCD) (Jenike *et al.*, 1983).

The involvement of 5-HT in the antidepressant effects of MAO inhibitors is also indirectly confirmed by the notion that MAO B selective inhibitors, such as deprenyl, induce only modest mood-enhancing effects, which may also be due to the action of this isoenzyme on oxidative stress (Bortolato *et al.*, 2008).

### **Role of MAO in behavioral regulation: human evidence**

#### ***Deletions of MAO A and MAO B in Norrie disease***

The first case of human MAO deficiency was originally reported in some patients afflicted by Norrie disease (ND). This genetic disorder is caused by a mutation of the NDP (Norrie disease pseudoglioma) gene, located in Xp 11.4, and is characterized by congenital blindness,

progressive hearing loss, and developmental delays in motor and cognitive skills (Warburg, 1975). Given the close proximity of NDP to MAO A and MAO B, some individuals afflicted by ND were found to carry deletions of MAO A and B (Sims *et al.*, 1989; Chen *et al.*, 1995). The loss of MAO function in ND results in high urinary concentrations of  $\beta$ -phenylethylamine and tyramine metabolites (Murphy *et al.*, 1990, 1991; Collins *et al.*, 1992). This alteration is accompanied by an array of atypical symptoms, such as growth failure, severe mental retardation, autistic-like behaviors, autonomic dysfunction and altered sleep patterns (Sims *et al.*, 1989; Murphy *et al.*, 1990; Collins *et al.*, 1992). Nevertheless, the predominance of the sensory deprivation in ND patients made it difficult to define the phenotypical outcomes of congenital MAO ablation.

#### ***MAO A total deficiency: Brunner syndrome***

In 1993, Brunner and colleagues described for the first time a genetic disorder caused by a point nonsense mutation in exon 8 of *Maoa* gene, which induced total deficiency of MAO A (Brunner syndrome) in several male subjects within a Dutch pedigree (Brunner *et al.*, 1993a, 1993b). The nosographic characteristics of this complex behavioral syndrome included mild mental retardation, impulsive aggressiveness, and violent responses to environmental stressors (Brunner *et al.*, 1993a, 1993b). The genetic defect in MAO A was also associated with a five-fold increase in urinary levels of 5-HT and O-metabolites of dopamine and norepinephrine.

#### ***MAO polymorphisms***

Several polymorphisms of the *Maoa* gene have been identified (Ozelius *et al.*, 1988; Black *et al.*, 1991; Hotamisligil and Breakefield, 1991; Hinds *et al.*, 1992) and employed in association studies for different psychiatric alterations (Shih and Thompson, 1999). The first report of an association between MAO A polymorphism and psychiatric disorder concerned the correlation between a long dinucleotide (CA)<sub>n</sub> repeat in intron 2 (Black *et al.*, 1991) and susceptibility to alcoholism/substance abuse in males (Vanyukov *et al.*, 1995).

Research has shown that some of the different polymorphisms of the *Maoa* gene may be associated with differences in enzymatic activity (Hotamisligil and Breakefield, 1991). In particular, the functional polymorphism of MAO A that has been characterized most extensively is a variable-number tandem repeat (VNTR) polymorphism, located 1.2kb upstream of the transcription initiation site

(Sabol *et al.*, 1998). Six different allelic variants have been characterized in the human population (Huang *et al.*, 2004; Sabol *et al.*, 1998), the most common of which presents three repeats (3R) and four repeats (4R) (Sabol *et al.*, 1998; Deckert *et al.*, 1999; Jonsson *et al.*, 2000). The first studies on VNTR variants in MAO A promoter consistently documented higher MAO A gene transcription and enzyme activity in association with the 4R allelic variant in transfected cells (Sabol *et al.*, 1998) and in cultures of human male skin fibroblasts (Denney *et al.*, 1999). In agreement with this finding, human studies have shown that the 3R variant is associated with behavioral features linked to low MAO A activity, such as impulsive aggressiveness and antisocial personality (Oreland *et al.*, 2007; Buckholtz and Meyer-Lindenberg, 2008). Conversely, 4R carriers display higher levels of 5-hydroxyindoleacetic acid (5-HIAA) in the cerebrospinal fluid (Jonsson *et al.*, 2000).

Furthermore, functional magnetic resonance imaging (fMRI) studies show a link between MAO A promoter VNTR variants and structural and functional differences in the brain (Meyer-Lindenberg *et al.*, 2006). Mutations in this promoter region have also been associated with a number of psychiatric disorders (Shih and Thompson, 1999; Chen, 2004).

Nevertheless, recent findings questioned the strength of the relation between different VNTR variants and MAO A activity. For example, *post-mortem* studies found a tendency for higher MAO A enzyme activity in brain samples from 4R adult carriers as compared to 3R counterparts, but this difference was not significant (Balciuniene *et al.*, 2002). Likewise, significant differences in MAO A activity (calculated as positron emission tomography (PET) time-activity data for [ $^{11}\text{C}$ ]clorgyline) between 3R and 4R adult subjects were found only in the primary visual cortex, but not in other brain regions (Alia-Klein *et al.*, 2008). An interesting possibility is that the 4R variant may actually be associated with a higher MAO A promoter than 3R in an age-dependent fashion, and the correlation between VNTR variants and MAO A activity may vary over time due to the exposure to a number of environmental factors that affect MAO A levels and activity, such as stress (Maura and Vaccari, 1975), diet changes (Jahng *et al.*, 1998), tobacco smoking (Fowler *et al.*, 1996), physical exercise (Morishima *et al.*, 2006), social environment (Filipenko *et al.*, 2002), and aging itself (Saura *et al.*, 1994). This hypothesis is corroborated by the finding that 3R-carriers with a history of early stress are more likely to commit violent crimes and to be diagnosed with conduct disorders (Caspi *et al.*, 2002).

Irrespective of the functional significance of MAO A polymorphic variants, these data point to a link between low-activity polymorphic variants and antisocial traits

(Manuck *et al.*, 2000). Indeed, MAO A activity in cortical and subcortical brain regions has been recently shown to be inversely correlated with the levels of self-reported aggression in men (Alia-Klein *et al.*, 2008). In line with this perspective, Brunner syndrome may be regarded as the end of a broad spectrum of antisocial manifestations correlated with low MAO A activity.

### **Role of MAO in behavioral regulation: animal evidence**

Our group and others have developed several lines of transgenic mice with nonsense mutations for each MAO isoenzyme. The characterization of the phenotypes of these animals has afforded substantial contributions to our understanding of the role of MAO in the regulation of behavior and brain functions and complemented the information from human studies.

#### **MAO A knockout mice**

The first line of MAO A knockout (KO) mice was generated through the serendipitous insertion of an interferon- $\beta$  cassette in exons 2 and 3 of the *Maoa* gene of C3H/HeJ mice (Cases *et al.*, 1995). The genetic defect followed an X-linked recessive line of transmission, and resulted in the total ablation of MAO A enzyme, leading to a complex array of abnormal morphological and behavioral phenotypes. MAO A KO pups display locomotor alterations, such as intense head bobbing, trembling, prolonged righting, and delay in the use of hindlimbs in swimming (Cases *et al.*, 1995; Cazalets *et al.*, 2000). This retarded maturation of the locomotor network is accompanied by alterations in the respiratory (Bou-Flores *et al.*, 2000) and sensory functions. Between days 11 and 16, MAO A KO mice exhibit locomotor hyperactivity, jumping and abnormal postures (Cases *et al.*, 1995). Adult MAO A KO mice display heightened levels of impulsive aggressiveness in the resident-intruder task and in other encounters with cage mates (Cases *et al.*, 1995; Chen *et al.*, 1999). This abnormal behavior is accompanied by marked reductions in exploratory activity and startle response, increased grasping during courtship, as well as enhanced motility in the forced swim test (Cases *et al.*, 1995). MAO A KO mice also show a number of alterations of emotional behaviors, such as increased tendency to stay in the center of an open arena (Cases *et al.*, 1995; Agatsuma *et al.*, 2006), higher levels of retention of aversive memories (Kim *et al.*, 1997) or retention of conditioned passive avoidance (Dubrovina and Zinov'ev, 2007). Nevertheless, they

do not show overt alterations of anxiety-like behaviors in the elevated plus maze (Popova *et al.*, 2001) and have low endocrine reaction to major stressors, such as physical restraint, water deprivation, cold temperature and chronic variable stress (Popova *et al.*, 2006). Since adult C3H mice are blind, some of these alterations have been questioned to depend on the specific characteristic of the strain. Nevertheless, the recent identification of a novel line of 129/Sv MAO A KO mice, harboring a nonsense point mutation of the exon 8 (in a position close to that altered in Brunner syndrome) substantially confirmed most of these alterations and strengthened their link with MAO A function (Bortolato *et al.*, 2008; Scott *et al.*, 2008). Taken together, the behavioral abnormalities observed in MAO A KO mice suggest a general impairment in environmental reactivity, with aberrant regulation of adaptive responses to stress, in a fashion reminiscent of that reported in Brunner syndrome patients.

The morphological analysis of neuronal patterns in the brain of MAO A KO mice indicates the possibility that their behavioral abnormalities may depend on the sensory deficits induced by the deficiency of this enzyme. Indeed, MAO A KO mice display alterations in the auditory and visual pathways (Upton *et al.*, 1999; Thompson, 2008), as well as the dysmorphogenesis of barrel fields in layer IV of the somatosensory cortex (S1) (Cases *et al.*, 1995). Barrel fields are the cortical representations of the mystacial vibrissae in the rodent snout, and their formation is dependent on the thalamocortical projections arising from the ventrobasal thalamic nuclei (Erzurumlu and Jhaveri, 1990). As whiskers play a key role in the regulation of exploratory behavior and thigmotaxis in rodents (Vincent, 1912; Luhmann *et al.*, 2005), the alterations of barrel

fields may underpin the abnormal responses in the open field in MAO A KO mice.

The neurochemical underpinnings of the phenotypical alterations in MAO A KO mice are still elusive. Interestingly, most behavioral and neuromorphological alterations observed in MAO A KO mice can be partially reproduced by chronic treatment with MAO A inhibitors during the early developmental stages, but not in adulthood. For instance, while pharmacological blockade of MAO A in adults fails to induce aggression, the same regimen in perinatal stages has been shown to produce a decrease in latency to attack in adult rats (Mejia *et al.*, 2002). Furthermore, early treatment with clorgyline induces behavioral alterations and impairments in thalamocortical development that resemble those observed in MAO A KO mice (Cases *et al.*, 1995; Boylan *et al.*, 2000). Conversely, we have shown that genetic reinstatement of MAO A in the forebrain of MAO A KO mice rescues their behavioral and morphogenetic abnormalities (Chen *et al.*, 2007).

Converging lines of evidence support a key role of 5-HT in the morphological and functional alterations in MAO A KO mice. In fact, early administration of p-chlorophenylalanine (PCPA), an inhibitor of 5-HT synthesis, reverses most aberrations in MAO A KO mice (Cases *et al.*, 1995; Upton *et al.*, 1999; Bou-Flores *et al.*, 2000). Indeed, hemizygous males displayed high levels of 5-HT and norepinephrine and modest increases in dopamine (Figure 4). Notably, the differences in 5-HT concentrations between MAO A KO mice and their wild-type (WT) counterparts are particularly elevated (up to 10-fold) during the early postnatal stages (Cases *et al.*, 1995; Lajard *et al.*, 1999).

**Figure 4** Levels of 5-HT, dopamine (DA), and norepinephrine (NE) are significantly higher in MAO A KO mice than WT conspecifics in an age-related fashion. Values from HPLC assays are expressed in pg/mg of wet brain and represent the mean  $\pm$  SEM. Modified from Cases *et al.* (12195).

The key role of 5-HT has been unequivocally shown in the dysmorphogenetic phenomena observed in MAO A KO mice. This notion is in agreement with extensive evidence showing that 5-HT has a trophic effect on neuronal progenitors (Lieske *et al.*, 1999; Lotto *et al.*, 1999) and on the morphogenesis of the cortex (Vitalis and Parnavelas, 2003) as well as sensory and locomotor networks (Nakajima *et al.*, 1998; Lebrand *et al.*, 2006), probably through activation of different sets of receptors. Accordingly, the abnormal formation of barrels of MAO A KO mice has been shown to be underpinned by excessive levels of 5-HT in the first week of postnatal life (Vitalis *et al.*, 1998), through activation of 5-HT<sub>1B</sub> receptors (Salichon *et al.*, 2001). In contrast, the morphological alterations of the respiratory centers in the medulla and the cervical phrenic motoneurons in MAO A KO are reversed by blockade of 5-HT<sub>2A</sub> receptors (Bou-Flores *et al.*, 2000).

The effects of MAO A inactivation on the 5-HTergic system have been analyzed in some investigations. In comparison with WT controls, MAO A KO mice show a reduced electric activity of 5-HTergic neurons, as well as down-regulation of 5-HTT, 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors (Shih *et al.*, 2000; Evrard *et al.*, 2002; Lanoir *et al.*, 2006).

The association of high levels of 5-HT and marked impulsive aggressiveness in MAO A KO mice is an interesting exception to the inverse relationship generally observed between these two phenomena (Coccaro, 1989). Indeed, our group found that aggression in MAO A KO mice is suppressed by ketanserin, the prototypical 5-HT<sub>2</sub> receptor antagonist, suggesting a key role of this receptor in the behavioral abnormalities caused by MAO A deficiency (Shih and Chen, 1999). 5-HT plays a pivotal role in the regulation of threat detection (Cools *et al.*, 2008) and in the pathophysiology of antisocial behavior (Deakin, 2003). Thus, high levels of 5-HT may set the emotional threshold for the enactment of aggressive responses, which on the other hand may reflect complex interactions with other neurotransmitters. Accordingly, both norepinephrine and dopamine have been extensively implicated in the regulation of impulsivity and aggression (Haller *et al.*, 1998; de Almeida *et al.*, 2005).

### **MAO B knockout mice**

In agreement with the low affinity of MAO B for 5-HT, mice deficient in this isoenzyme display only significant changes in brain levels of  $\beta$ -phenylethylamine, which are accompanied by behavioral disinhibition and alterations in stress-related and anxiety-like responses (Cases *et al.*, 1995; Bortolato *et al.*, 2009). The phenotypical

characteristics of MAO B KO mice have been described elsewhere (Bortolato *et al.*, 2008, 2009).

### **MAO A/B knockout mice**

We have recently characterized and developed a novel MAO AB KO line, harboring a spontaneous point mutation of MAO A and ablation of MAO B (Chen *et al.*, 2004). These mice display an array of unique phenotypes, which cannot be recapitulated by a summation of MAO A KO and MAO B KO. 5-HT, norepinephrine, dopamine and  $\beta$ -phenylethylamine levels are highly increased in comparison to either the MAO A or the MAO B KO mice. Furthermore, the behavioral phenotype in these mutant animals is characterized by low novelty-induced locomotion, high levels of anxiety-like behaviors in the elevated plus maze, and low latency to attack in the resident-intruder paradigm, which may be likened to an increase in impulsivity (Chen *et al.*, 2004). The role of 5-HT in these alterations of emotional behaviors, however, is still poorly understood.

### **Conclusions**

MAO is the key enzyme in 5-HT degradation, and its regulation is fundamental in the management of 5-HT signaling. By means of several complementary approaches, research has provided a great deal of knowledge about the structure and function of both MAO isoenzymes and their key role in the regulation of brain architecture and behavior. These studies have set the stage for future investigations which will further our understanding of the role of these enzyme in the pathophysiology of several mental disorders and examine the specific role of 5-HT in the morphological and behavioral outcomes of MAO inactivation.

### **Acknowledgements**

# Cellular Effects of Serotonin in the CNS

Rodrigo Andrade<sup>\*,1</sup> and Sheryl G. Beck<sup>2</sup>

<sup>1</sup>*Department of Pharmacology, Wayne State University School of Medicine, E. Canfield, Detroit, Michigan*

<sup>2</sup>*Abramson Research Center, Children's Hospital of Philadelphia, University of Pennsylvania, Philadelphia, Pennsylvania*

**Abstract:** Serotonergic neurons innervate the entire neuroaxis, thus allowing serotonin to regulate the function of most CNS neurons. Work during the past two decades has made clear that the specific form taken by this regulation is dependent on the complement of serotonin receptors expressed by each cell. This general principle is now being extended to different cell types within defined neuronal networks to understand how serotonin regulates network function. In this chapter we review progress along this front in two intensely studied areas, the hippocampus and the cerebral cortex, and highlight areas of progress while noting outstanding issues that await elucidation.

**Keywords:** serotonin, hippocampus, cortex, 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub>, 5-HT<sub>3</sub>, 5-HT<sub>4</sub>, 5-HT<sub>7</sub>, pyramidal neurons, GABAergic interneurons.

**Abbreviations:** 1AKO, 5-HT<sub>1A</sub> receptor knockout mouse; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; CA, cornu ammonis; CB, calbindin; CCK, cholecystokinin; CNS, central nervous system; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; DNQX, 6,7-dinitroquinoxaline-2,3-dione; eEPSC, evoked excitatory postsynaptic current; G<sub>α</sub>, G-protein alpha subunit; GABA, gamma aminobutyric acid; GIRK, G-protein-mediated inward rectifying potassium channel; GPCR, G-protein-coupled receptors; 5-HT, 5-hydroxytryptamine, serotonin; Kir3.x, inward rectifying potassium channel; Kv1.2, delayed rectifier potassium channel; NMDA, N-methyl-D-aspartate; PV, parvalbumin; sIPSC, spontaneous inhibitory postsynaptic current; SLM, stratum lacunosum moleculare; SO, stratum oriens; SP, stratum pyramidale; SR, stratum radiatum; TTX, tetrodotoxin; WT, wild type.

## Introduction

What does serotonin do? We hear that question often, from colleagues, from students, from neighbors, even from fellow passengers in airplanes. And although the question has different meanings depending on who asks it, we would like to argue that ultimately the answers collapse around the central issue of what serotonin does to the functioning of central neuronal networks.

This idea, which admittedly appears quite myopic on first encounter, is grounded in one of the central concepts underlying modern neurobiology: that there is a direct correspondence between the coordinated activity of central neuronal networks and behavior – in other words, that behavior is the macroscopic embodiment of brain activity. Seen in this manner, to ask about the function of serotonin in health and disease is also to ask how serotonin functions within the context of neuronal networks. We believe

this holds true even if at the present time our understanding of the relationship between neuronal activity and behavior remains primitive. Thus, in this chapter we would like to argue that it is not that serotonin regulates sleep, hunger, movement or anxiety, to name just a few. Rather, what serotonin does is help code for the specific functional states of central networks that create the substrate upon which those specific behaviors take place. Admittedly, in this formulation, the function of serotonin does not lend itself well to descriptors arising from our everyday experience. However, we believe that such a formulation provides a fruitful framework for understanding how serotonin may be involved in almost everything.

This formulation emerges from our own work on the cellular electrophysiology of serotonin. However, its core is grounded on three fundamental features of serotonergic systems that we believe frame any attempt to understand what serotonin does in the brain.

The first feature that is singularly striking about serotonin as a neurotransmitter in the mammalian brain is that a relatively small number of serotonin-synthesizing neurons

\*Corresponding author  
E-mail: randrade@med.wayne.edu

in the brainstem innervate nearly the entire neuroaxis (Dahlstrom and Fuxe, 1964; Steinbusch, 1981; Jacobs and Azmitia, 1992). Of course this is not a unique feature of the serotonergic system; one only needs to consider the noradrenergic innervation of the brain originating from locus coeruleus and other adrenergic nuclei to see the pattern replicated. Nevertheless, this is a central feature of the organization of serotonergic systems in the brain. This implies, as pointed out by others (such as Jacobs and Fornal, 1999), that whatever serotonin does must be quite general.

The second feature is that the activity of serotonergic neurons is associated with the behavioral state of the animal (Jacobs and Azmitia, 1992; Jacobs and Fornal, 1999; Jacobs *et al.*, 2002). This key observation, which dates back to the seminal studies of Jacobs and associates in the late 1970s, indicates that whatever general function serotonin plays in the brain is somehow related to the global behavioral state of the animal, although a more specific association with motor activity has also been suggested (Jacobs and Fornal, 1999; Jacobs *et al.*, 2002).

The third telling feature of serotonergic neurotransmission is that serotonin acts in the brain predominantly, albeit not exclusively, through G-protein-coupled receptors (GPCRs; the exception is the 5-HT<sub>3</sub> receptor). GPCRs are not well suited to carry millisecond to millisecond synaptic operations, the elementary building blocks of computational operations. Rather, these receptors regulate the way neurons, the basic computational units of neuronal networks, function. This realization, codified in the 1980s through groundbreaking work on invertebrate experimental preparations (reviewed by Harris-Warrick and Marder, 1991), brought to close the decades-long controversy that asked whether serotonin (or dopamine, etc.) was excitatory or inhibitory. These insights ushered a reformulation of how we think about neurotransmitters that act predominantly through GPCRs, and brought forth the idea that by modifying the properties of neurons, neurotransmitters acting through GPCRs allow neuronal networks to produce varying outputs.

Together, these ideas led to a reconceptualization of what serotonin does in the brain. For, if behavioral states represent the organism-level counterparts of functional states of central neuronal circuits, then the function of serotonin in the brain is probably best understood as contributing to the coding for these functional states. In other words, what serotonin does in the brain is to help orchestrate neuronal function such that neuronal networks operate in a manner that executes behavior appropriate to the circumstances. As such, serotonin forms part of an ensemble of neurotransmitters specifying the functional states of the central neuronal networks that define the universe of behavioral states available to an organism.

But how can serotonin accomplish this task? Studies examining the electrophysiological effects of serotonin in central neurons suggest that this is made possible by the existence of multiple serotonin receptor subtypes and the ability of neurons to co-express them. The co-expressed receptors act as translators that link localized rises in serotonin concentration to the activation of clusters of cellular processes defined by the specific combination of serotonin receptor subtypes present at a given site. This allows serotonin to regulate central neurons in a manner that is specific and flexible, as the effects in each cell reflect the combinatorial action of multiple serotonin receptors each signaling a qualitatively invariant response. And, of course, within specific neuronal networks, each cell type expresses a unique amalgamation of receptors. We believe this is how a highly divergent neuronal system that releases serotonin onto a large fraction of the neurons in the brain can attain the flexibility needed to tune the function of neuronal circuits as needed to help code the behavioral state of the organism.

But of course these are all theoretical considerations. How are these principles implemented in real neuronal networks? In this chapter we provide some examples of how this may happen in two areas of the brain, the hippocampus and the cerebral cortex. We do so, fully cognizant that there is a vast and extraordinary literature on the effects of serotonin on many different neural networks, and also painfully aware that in writing this review we are forced to leave most of it out. We ask for the forgiveness of our colleagues. We focus on these two areas not only because we work in them, but also because a strong case can be made that they represent the best extant example we have of how serotonin, through the use of different receptor subtypes, can regulate central neuronal networks.

## The hippocampus

It is probably not surprising that the hippocampus is the brain area where the effects of serotonin have been most thoroughly examined. This reflects the simple fact that the 'light is better' in the hippocampus. Among the principal advantages of working in the hippocampus is the fact that the basic circuitry of this region is organized along parallel lamellae, each containing the basic functional elements of the trisynaptic hippocampal circuit including the granule cells of the dentate gyrus, the pyramidal cells of the CA3 and CA1 regions and their synaptic connections. Equally important from an experimental point of view, the cell bodies of the principal cells, the granule cells of the dentate gyrus and the pyramidal cells of the CA fields, are arranged in well-defined layers and give rise to consistently oriented apical and basal dendrites, while afferent

and efferent pathways are generally segregated within specific layers. This precise cytoarchitecture makes it easy for electrophysiologists to stimulate and record from identified cells or even isolated dendrites, and study the properties of select synapses.

From a functional standpoint, all the principal neurons of the hippocampal trisynaptic circuit use glutamate as a neurotransmitter and thus are excitatory. As such, this circuit can be understood as a three-stage processing network, with a main input comprising the entorhinal afferents to the dentate gyrus and a main output comprising the CA1 projection to the subiculum. However, it is important to understand that the function of this circuit is dramatically shaped by GABAergic interneurons. These cells are highly heterogeneous in terms of their soma location, axonal and dendritic arborizations, neurochemical content (neuropeptides, calcium-binding proteins) and electrophysiological characteristics, and this heterogeneity leads to major differences in the functionality of these interneurons (reviewed by Ascoli *et al.*, 2008; Klausberger and Somogyi, 2008). Although at the present time it is not known precisely how many different types of interneurons are present in the hippocampus, it is clear that these cells shape information flow through the trisynaptic hippocampal circuit (Ascoli *et al.*, 2008; Klausberger and Somogyi, 2008).

### Pyramidal cells

Anatomical studies suggest strongly that most cell types in the hippocampus, including the pyramidal cells of the CA fields as well as the granule cells of the dentate gyrus, may be regulated by serotonin. Thus, the hippocampus receives a robust serotonergic innervation that originates primarily from the median raphe, although both the median and the dorsal raphe contribute fibers to the innervation of the ventral hippocampus. Serotonergic fibers are found throughout all fields of the hippocampus, but are most numerous in the stratum radiatum and stratum lacunosum moleculare of the CA1 and CA3 regions (Freund *et al.*, 1990; Gulyas *et al.*, 1999). Interestingly, 5-HT fibers appear to make very few synaptic specializations with the pyramidal cells on either soma or dendrites (Gulyas *et al.*, 1999), although there are 5-HT receptors on the pyramidal cell processes. This indicates that volume or paracrine transmission may be the predominant mode of transmission between the serotonergic fibers and serotonin receptors expressed on hippocampal pyramidal cells and at least some types of interneurons (Figure 1).

Seeking to understand how serotonin regulates hippocampal function, initial work focused on pyramidal cells

of the CA1 region and characterized a serotonin-induced hyperpolarization that resulted in inhibition of the population spike (Segal, 1980; Beck *et al.*, 1985; Andrade and Nicoll, 1987). Subsequent work showed that this effect was mediated by 5-HT<sub>1A</sub> receptors (Segal, 1980; Beck *et al.*, 1985; Andrade and Nicoll, 1987) acting through G $\alpha_{i/o}$  and leading to the activation of a potassium current carried through GIRK (Kir3.x) potassium channels (Andrade and Nicoll, 1987; Beck *et al.*, 1992) (Figure 2C). A similar 5-HT<sub>1A</sub> receptor-mediated hyperpolarizing effect is seen in granule cells of the dentate gyrus (Piguet and Galvan, 1994) and pyramidal neurons of the CA3 region. However, in this latter area the 5-HT<sub>1A</sub> response is less potent than the response in CA1, but greater in magnitude, even though the density of the receptors appears to be less (Beck *et al.*, 1992). Differences notwithstanding, these results showed that 5-HT<sub>1A</sub> receptors signal reductions in cellular excitability in each of the principal cells of the hippocampal trisynaptic circuit (Figure 2C).

Subsequent studies indicated that 5-HT<sub>1A</sub> receptors are not the sole serotonin receptors expressed on pyramidal cells (Andrade and Nicoll, 1987; Colino and Halliwell, 1987) and CA1 pyramidal neurons were shown to also express 5-HT<sub>4</sub> receptors (Andrade and Nicoll, 1987; Andrade and Chaput, 1991; Torres *et al.*, 1994) while CA3 pyramidal neurons were shown to express 5-HT<sub>4</sub> and 5-HT<sub>7</sub> receptors (Bacon and Beck, 2000). Both of these receptors couple to G $\alpha_s$ , activate adenylate cyclase and protein kinase A, and signal an inhibition of the calcium-activated potassium current that mediates the slow after-hyperpolarization present in these cells (Figure 2B). Since this current acts as a brake on the ability of the pyramidal cells to fire repetitively, its suppression by 5-HT<sub>4</sub> and 5-HT<sub>7</sub> receptors results in a large facilitation in the ability of strong stimuli to drive cell firing. As such, 5-HT<sub>4</sub> and 5-HT<sub>7</sub> receptors could be considered as signaling 'excitatory' responses to serotonin, an observation that initially seemed at odds with the observation that these same cells also expressed 'inhibitory' 5-HT<sub>1A</sub> receptors. This paradox was resolved with the demonstration that the co-activation of 5-HT<sub>1A</sub> and 5-HT<sub>4</sub> receptors resulted in a large change in neuronal gain, a measure of how neurons encode excitatory input into firing output, such that weak excitatory stimuli are suppressed while strong stimuli are facilitated (Andrade and Nicoll, 1987).

Finally, pyramidal neurons of the CA1, but not the CA3, field express 5-HT<sub>1B</sub> receptors that are targeted to their axonal projection terminals located in the subiculum (Ait *et al.*, 1995). Activation of these receptors inhibits glutamate-mediated synaptic transmission in this region (Boeijinga and Boddeke, 1993) by reducing the probability of glutamate release at individual synaptic terminals (Figure 2E). One interesting feature of this presynaptic

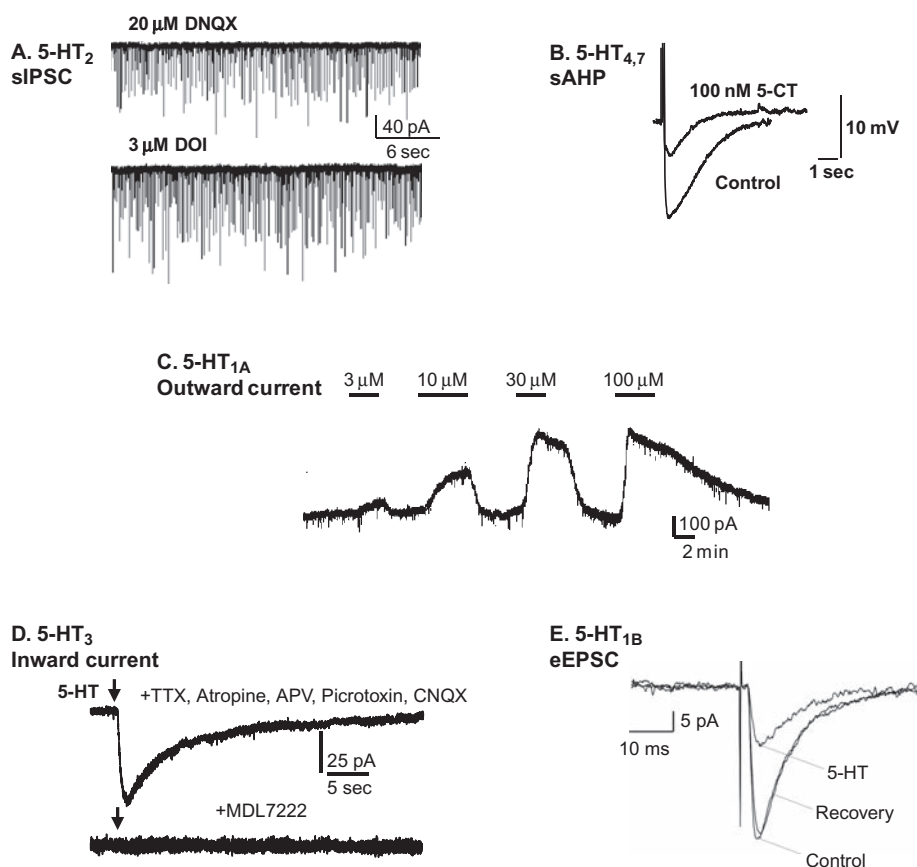

**Figure 1** Cartoon depicting the known interactions of serotonin with components of the CA1 hippocampal subfield. The pyramidal cell, in gray, is the principal neuron surrounded by three different types of GABAergic interneurons (in gradient gray). The 5-HT innervation, depicted in black, is found in all the layers, but is most numerous in the stratum radiatum (SR) and stratum lacunosum moleculare (SLM). Current evidence suggests that a large fraction of serotonin fibers do not make specialized synaptic contact with the pyramidal or the parvalbumin (PV)-expressing GABAergic interneurons. What is depicted, therefore, is release of 5-HT from axonal terminals into the extrasynaptic space. On the pyramidal cells there are 5-HT<sub>1A</sub> and 5-HT<sub>4</sub> receptors. On the GABA/CCK and GABA/CB interneurons serotonin does make synaptic contacts that are thought to activate the 5-HT<sub>3</sub> receptors. 5-HT<sub>2</sub> receptors are known to increase GABA synaptic activity, but it is not known exactly on which GABA interneuron type they are located; in this illustration we have placed it on a calbindin interneuron but such location is conjectural. 5-HT<sub>1B</sub> receptors are located in the subiculum on synaptic terminals originating from CA1 pyramidal cells.

inhibition is that it is frequency dependent, such that high-frequency volleys can be expected to be relatively unaffected by serotonin (Boeijinga and Boddeke, 1996). This feature dovetails with the serotonin-induced change in gain at the level of the soma, and suggests a general principle for the effects of serotonin on the hippocampal trisynaptic circuit – namely, that serotonergic activity results in a change in the functioning of this circuit such that transmission of weak/low-frequency stimuli is suppressed by serotonin acting on 5-HT<sub>1A</sub> receptors located on the dendrites of the principal neurons, and on 5-HT<sub>1B</sub> receptors located on the CA1 terminals in subiculum, while strong/high-frequency stimuli are facilitated in the CA1–CA3 subfield through the activation of 5-HT<sub>4</sub> and 5-HT<sub>7</sub> receptors. And of course the frequency dependence of the 5-HT<sub>1B</sub> receptor-mediated presynaptic inhibition allows unfettered transmission of such strong/high-frequency

action potential firing at the output stage in subiculum. In other words, serotonin acting through multiple receptors in the different hippocampal fields appears to shape the functional mode of the trisynaptic circuit.

### *GABAergic interneurons*

Unfortunately much less is known about the effects of serotonin on the different types of GABAergic interneurons, although it is clear that serotonergic fibers show remarkable selectivity in their innervation. Thus, for example, serotonergic fibers often follow the dendrites and cell bodies of calbindin neurons in stratum radiatum and stratum oriens (Freund *et al.*, 1990; Gulyas *et al.*, 1999). Cholecystikinin- and parvalbumin-expressing interneurons both make perisomatic contacts

**Figure 2** Electrophysiological effects elicited by activation of different 5-HT receptors in the CA1 subfield of the hippocampus. (A) Activation of 5-HT<sub>2</sub> receptors elicits an increase in GABAergic synaptic activity onto CA1 pyramidal neurons. This cell was voltage clamped at  $-60$  mV, and spontaneous GABAergic inhibitory synaptic currents (sIPSCs, downward deflections) were isolated by the administration of the AMPA receptor antagonist DNQX. Administration of the 5-HT<sub>2</sub> agonist DOI increases the frequency and amplitude of the sIPSCs. (B) Activation of the 5-HT<sub>4,7</sub> receptors produces a decrease in the amplitude of the slow afterhyperpolarization (sAHP) that follows a train of action potentials elicited by a depolarizing current pulse. (C) Activation of 5-HT<sub>1A</sub> receptors elicits a concentration-dependent outward current mediated by activation of GIRK (Kir3.x) potassium channels. (D) Activation of 5-HT<sub>3</sub> receptors in the presence of the action potential blocker TTX, and antagonists for muscarinic cholinergic (atropine), NMDA (APV), AMPA (CNQX), and GABA<sub>A</sub> (picrotoxin) receptors, elicits an inward current that can be blocked by the 5-HT<sub>3</sub> antagonist MDL7222. (E) Activation of 5-HT<sub>1B</sub> receptors located on the presynaptic terminals of the CA1 pyramidal cells inhibits evoked excitatory synaptic transmission (eEPSC) onto pyramidal neurons in the subiculum.

with pyramidal cells, but only cholecystokinin-expressing interneurons receive 5-HT synaptic contacts (Freund *et al.*, 1990; Gulyas *et al.*, 1999). This anatomical specificity hints at a precise regulation of different interneuron types by serotonin.

From an electrophysiological standpoint, serotonin elicits highly variable effects on over 64 percent of GABAergic interneurons (Parra *et al.*, 1998), a variability that is likely to reflect the functional heterogeneity of these cells. The clearest findings concern parvalbumin- and cholecystokinin-expressing interneurons, which play a significant role in controlling gamma and theta oscillations (Freund, 2003; Klausberger *et al.*, 2003; Freund and Katona, 2007) through a strong perisomatic

innervation of the pyramidal cells. Interestingly, while both of these cell types make anatomically similar connections with pyramidal cells, they differ in function. Thus parvalbumin-expressing interneurons are proposed to operate in a precise clockwork manner maintaining the constant theta activity, in a non-plastic manner with little interference from afferent input. In contrast, the cholecystokinin-expressing interneurons are susceptible to subcortical pathway input regarding the motivational, the emotional and the general physiological state of the animal. Remarkably, cholecystokinin- but not parvalbumin-expressing interneurons express 5-HT<sub>3</sub> receptors (Morales and Backman, 2002). Of course, activation of the 5-HT<sub>3</sub> receptors elicits a

fast inward current (Figure 2D) that depolarizes these GABAergic interneurons (McMahon and Kauer, 1997) and thus can be expected to increase inhibitory input to the soma of the pyramidal cell, reducing the likelihood of action potential initiation and thus directly influencing gamma and theta activity. This suggests a mechanism through which serotonin could modify the function of the perisomatic network.

Other classes of interneurons are also likely to be regulated by serotonin acting on other receptor subtypes, thus allowing for their modulation. For example, 5-HT<sub>2</sub> receptors increase GABAergic synaptic activity, but it is unknown on which interneurons they are located (Figure 2A). Anatomical studies indicate very precise or selective innervation of only the calbindin- and cholecystokinin-expressing interneurons, but other physiological studies indicate a more global influence of serotonin on interneurons (Parra *et al.*, 1998), perhaps through volume transmission. Thus clearly one of the key tasks at hand is to understand if and how serotonin regulates the function of the other types of GABAergic interneurons in the hippocampus. This knowledge, coupled with a better understanding of the role of interneurons in shaping hippocampal function, should allow us to begin the development of a mechanistic picture of how serotonin regulates hippocampal circuits and hippocampal function.

### Development

Serotonin fibers innervate the hippocampus during gestation, and serotonin receptors, most notably those of the 5-HT<sub>1A</sub> subtype, are detectable at birth and increase thereafter (Patel and Zhou, 2005; Deng *et al.*, 2007). A series of recent studies using genetically engineered mice has revealed a remarkable role for this serotonergic receptor in terms of influencing the development of the hippocampus. 5-HT<sub>1A</sub> receptor knockout (1AKO) mice were generated by targeted gene disruption in three different laboratories (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998). In parallel to the complete lack of 5-HT<sub>1A</sub> receptors demonstrated through receptor binding in 1AKO mice, all these mouse lines showed elevated levels of anxiety in several different animal models (Heisler *et al.*, 1998; Ramboz *et al.*, 1998; Parks *et al.*, 1998). To better understand the basis for this phenotype, Gross and colleagues (2002) used gene targeting technology to generate mice with conditional expression of the 5-HT<sub>1A</sub> receptor in forebrain regions, including the hippocampus, amygdala and frontal cortex. This approach allowed for the rescue of functional 5-HT<sub>1A</sub> receptors (i.e., the rescue of the 5-HT<sub>1A</sub>-receptor induced hyperpolarization) in the forebrain. Remarkably, these 5-HT<sub>1A</sub> 'rescued' mice behaved like WT mice in

the behavioral tests for anxiety (Gross *et al.*, 2002). If the receptor was rescued when the mouse was an adult or after postnatal day 21, the anxiety phenotype was still present, indicating that the 5-HT<sub>1A</sub> receptor needs to be present during postnatal days 0–21 to relieve the anxiety phenotype. These results point to a key role for 5-HT<sub>1A</sub> receptors during development, most likely at the level of the hippocampal circuitry, and suggest that disruption of serotonergic function in this area during development can lead to long-lasting behavioral changes. Future studies will have to be conducted to determine exactly what changes occur during this critical time period when 5-HT is not present that lead to the anxious phenotype.

### The cerebral cortex

In comparison to the hippocampus, with its diaphanous cytoarchitecture, the cerebral cortex presents a much more complex target for understanding the effects of serotonin. As such, this section represents an even more tentative progress report.

Like the hippocampus, the cerebral cortex contains two main neuronal cell types, glutamate-releasing excitatory pyramidal neurons and GABA-releasing inhibitory interneurons. Pyramidal neurons are the predominant cell type, and constitute the only projection cell of the cerebral cortex. Histologically, pyramidal neurons are arranged in multiple cell layers, generally six, with each layer having a preferential projection target. Thus, in general, layer VI projects to thalamus, layer V projects predominantly to subcortical structures, and the more superficial layers II–III to ipsi- and contralateral cortex. Layer IV, when present, receives thalamic input. Recent work, however, suggests that within this broad pyramidal cell classification lies considerable molecular and functional heterogeneity (Molnar and Cheung, 2006; Sugino *et al.*, 2006; Molyneaux *et al.*, 2007; Leone *et al.*, 2008). Furthermore, as in hippocampus (Klausberger and Somogyi, 2008), GABAergic interneurons fall into several distinct anatomical and functional classes.

In general, anatomical studies have shown that the serotonergic innervation of the cerebral cortex is extensive, and fairly homogeneous (Lidov *et al.*, 1980). However, it is important to note that the expression of different serotonin receptor subtypes displays considerably variation from cortical area to cortical area. Thus, for example, in adult rats 5-HT<sub>2A</sub> receptors show a steep anteroposterior expression gradient (Lopez-Gimenez *et al.*, 1997), while 5-HT<sub>7</sub> receptors are essentially absent from the prefrontal cortex in adult rodents but are reasonably well expressed at more posterior levels of the cingulate (Gustafson *et al.*, 1996). This heterogeneity is not surprising given the

functional heterogeneity of the cortex. However, it does make it difficult to provide a single answer to the question of what serotonin does to cortical networks, as the answer will clearly depend on the area of cortex in question.

### *Pyramidal cells*

These limitations notwithstanding, considerable progress has been made elucidating the actions of serotonin in particular areas of the cerebral cortex. Several groups have focused on pyramidal cells of the prefrontal, somatosensory and visual cortices, and in this section we emphasize the work in these areas. The prefrontal cortex in particular has emerged in the last decade as a key brain region in the organization of behavior (Buckner *et al.*, 2008; Tanji and Hoshi, 2008), and has been implicated in a variety of pathophysiological processes ranging from drug abuse to autism and schizophrenia (see, for example, Bachevalier and Loveland, 2006; Tan *et al.*, 2007; Buckner *et al.*, 2008; Clay *et al.*, 2008; Tanji and Hoshi, 2008). As such, it has received considerable attention from serotonin physiologists working predominantly in rodent model systems. This has resulted in substantial strides in our understanding of the effects of serotonin in this region. However, it is important to realize that while there are important similarities in terms of connectivity and function between the prefrontal cortex of rodents and of primates, there are also some important differences (Uylings *et al.*, 2003). Furthermore, there are significant cytoarchitectonic differences – most notably, the absence of a well-developed granular layer IV in rodent prefrontal cortex (van Eden and Uylings, 1985). It will be important to keep these differences in mind as we seek to use the knowledge gained in rodent model systems to understand the pathophysiology of the prefrontal cortex and its relationship to serotonergic mechanisms.

The effects of serotonin on cortical pyramidal cells, and especially those of layer V, have been assessed by several groups during the past two decades. There is a general consensus that administration of serotonin results in a large increase in spontaneous synaptic activity that is accompanied by variable changes in membrane potential and a large modulation of neuronal gain, a measure of how effectively neurons transform excitatory drive into firing (Araneda and Andrade, 1991; Spain, 1994; Aghajanian and Marek, 1997; Zhou and Hablitz, 1999; Foehring *et al.*, 2002; Beique *et al.*, 2004a, 2004b, 2007; Villalobos *et al.*, 2005; Zhang and Arsenault, 2005; Higgs *et al.*, 2006). The simplest of these effects, the changes in membrane potential and gain, have been extensively studied, and it is now apparent that they can be accounted for, at least in adult animals, by the co-expression of 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub>

receptors in pyramidal neurons. A large fraction of layer V pyramidal neurons in the prefrontal cortex express 5-HT<sub>1A</sub> receptors that signal a membrane hyperpolarization that can be expected to suppress excitability (Araneda and Andrade, 1991; Martin-Ruiz *et al.*, 2001; del Burgo *et al.*, 2008). However, most pyramidal neurons also co-express 5-HT<sub>2A</sub> receptors (Araneda and Andrade, 1991; Vysokanov *et al.*, 1998; Martin-Ruiz *et al.*, 2001), which generally signal a variable membrane depolarization and inhibit a calcium-activated potassium current (Araneda and Andrade, 1991; Villalobos *et al.*, 2005; Zhang and Arsenault, 2005). As in the hippocampus, this co-expression of receptors signaling opposite effects on excitability was initially puzzling. However, because the slow calcium-activated potassium current limits the ability of a neuron to transform a sustained excitatory drive into spiking, its inhibition by serotonin acting on 5-HT<sub>2A</sub> receptors effectively increases a neuron's gain (Araneda and Andrade, 1991; Zhang and Arsenault, 2005). Furthermore, the balance between hyperpolarizing and depolarizing influences can effectively adjust the excitatory input range over which neurons can encode excitatory input into firing activity. This suggests that the co-expression of 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> in pyramidal cells allows serotonin to regulate how cells transform excitatory input into firing in a manner that is easily tunable by changing receptor expression levels (Araneda and Andrade, 1991).

Interestingly, previous studies have shown that uncoordinated synaptic noise can effectively increase neuronal gain (Higgs *et al.*, 2006, and references therein). Since serotonin very strongly facilitates spontaneous synaptic activity, this effect alone would be expected to increase gain in pyramidal cells irrespective of any changes in neuronal properties. It is tempting to speculate that perhaps these two mechanisms could synergize in pyramidal cells, although experimental confirmation of this conjecture is missing at this time (W.J. Spain, personal communication).

While the direct effects of serotonin on membrane excitability outlined above have been understood for well over a decade, the very robust increase in spontaneous glutamate receptor-mediated synaptic activity elicited by serotonin in prefrontal cortex has proven much more contentious. Many studies have shown that serotonin induces this increase in glutamate release through the activation of 5-HT<sub>2A</sub> receptors (Aghajanian and Marek, 1999; Marek and Aghajanian, 1999; Zhou and Hablitz, 1999; Foehring *et al.*, 2002; Beique *et al.*, 2004b, 2007). However, the simplest explanation for such an effect, namely that serotonin excited pyramidal cells, was thought unlikely given the small 5-HT<sub>2A</sub> receptor-induced depolarization generally seen in pyramidal neurons. Instead it was proposed that the activation of 5-HT<sub>2A</sub> receptors on

pyramidal cells led to the release of a retrograde message that excited thalamocortical afferents, by inhibiting Kv1.2 channels (Zhou and Hablitz, 1999; Lambe and Aghajanian, 2001). Recent work, however, has shown this possibility to be untenable (Beique *et al.*, 2007); instead, it has proposed that 5-HT<sub>2A</sub> receptors excite a population of pyramidal cells in cortex that had previously gone unsampled, and that it is the excitation of this population of pyramidal cells that accounts for the increase in glutamate release widely observed in this region (Beique *et al.*, 2007) (Figure 3). These results emphasize the importance of addressing the functional heterogeneity of pyramidal cells when considering the effects of serotonin in cortex.

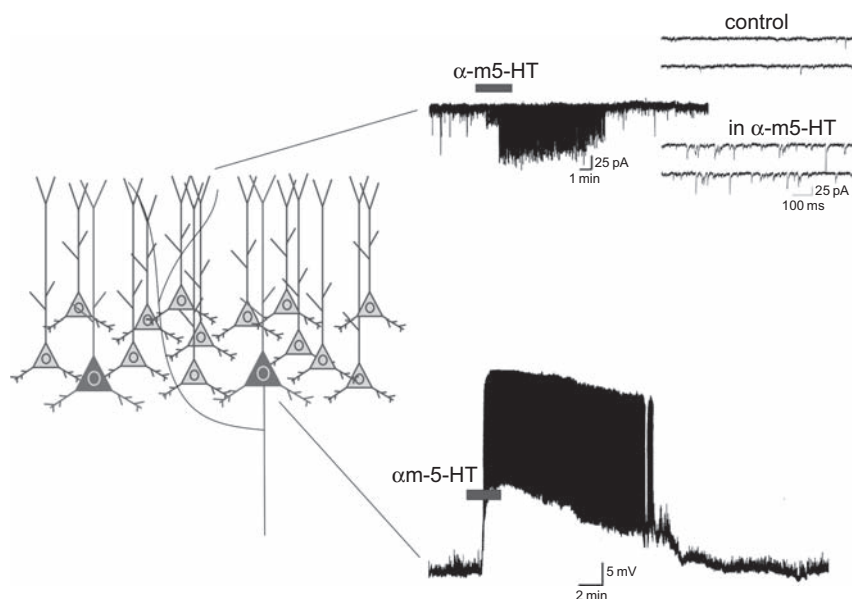

In addition to these effects on pyramidal cells, administration of 5-HT to cortical slices also inhibits evoked excitatory synaptic transmission onto pyramidal neurons (Tanaka and North, 1993; Rhoades *et al.*, 1994; Murakoshi *et al.*, 2001; Laurent *et al.*, 2002; Torres-Escalante *et al.*, 2004). This effect reflects a presynaptic inhibitory effect of serotonin on glutamate release that is mediated by 5-HT<sub>1B/D</sub> receptors (Tanaka and North, 1993; Rhoades *et al.*, 1994; Laurent *et al.*, 2002). Unfortunately, the exact identity of the afferents expressing the 5-HT<sub>1B</sub> receptors and thus inhibited by serotonin is unclear. In young animals, it has been suggested that serotonin acting via 5-HT<sub>1B</sub> receptors regulates the activity of thalamocortical axons innervating somatosensory cortex (Rhoades

*et al.*, 1994; Laurent *et al.*, 2002). However, since current technical limitations preclude the selective stimulation of different cortical afferents, it is not known whether these findings can be generalized to different ages and to different cortical areas. In any case, the observation that administration of serotonin increases spontaneous glutamate synaptic activity in prefrontal and somatosensory cortices suggests that this presynaptic inhibitory effect in cortex must exhibit at least some selectivity for specific populations of afferents.

### Interneurons

Cortical interneurons constitute a diverse group of GABAergic neurons whose function is to sculpt the functional properties of pyramidal cell networks (Bacci *et al.*, 2005; Klausberger and Somogyi, 2008). While the exact number of interneuron classes is still uncertain, it is now clear that different cortical interneurons identified on morphological grounds or based upon the expression of molecular markers also represent distinct functional classes. Thus it will come as no surprise that different classes of cortical interneurons also express different serotonin receptors or possibly combinations of serotonin receptors.

Our understanding of the effects of serotonin on different classes of interneurons is still in its infancy, but has

**Figure 3** Serotonin increases glutamate release in the prefrontal cortex by exciting a subpopulation of deep layer V pyramidal neurons. Administration of the 5-HT<sub>2A</sub> agonist alpha-methyl serotonin depolarizes and excites the large pyramidal cells of deep layer V in the rat prefrontal cortex. In contrast, administration of this agonist elicits only a modest depolarization/inward current in the smaller pyramidal neurons of upper layer V but elicits a large increase in spontaneous glutamate-mediated synaptic activity onto these cells. This effect is thought to reflect the excitation of the deep layer V cells that synapse onto the more superficial pyramidal neurons in this region.

been greatly helped by the identification of molecular markers that identify subsets of interneurons (Bacci *et al.*, 2005). For example, one class of large cortical interneurons is identifiable by the expression of parvalbumin. These cells correspond to the classic chandelier and basket cells innervating the soma and initial segment of pyramidal cells, which allows them to function as key regulators of the output (firing) of pyramidal cells. Anatomical studies conducted in the prefrontal cortex have shown that these cells robustly express 5-HT<sub>2A</sub> receptors and 5-HT<sub>2C</sub> receptors (Willins *et al.*, 1997; Jakab and Goldman-Rakic, 2000; de Almeida and Mengod, 2007; Liu *et al.*, 2007) but express 5-HT<sub>1A</sub> receptors only infrequently (de Almeida and Mengod, 2008). In contrast, in this same region, a different class of interneurons identifiable by the expression of calbindin expresses 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>3</sub> receptors (Jakab and Goldman-Rakic, 2000; de Almeida and Mengod, 2007, 2008).

Electrophysiological studies show patterns of response that are consistent with the presence of all these receptor subtypes in cortical interneurons (Zhou and Hablitz, 1999; Foehring *et al.*, 2002; Xiang and Prince, 2003). However, because the electrophysiological criteria generally used in these studies are insufficient to identify specific interneuron subtypes, these results are difficult to place in a functional context. Thus clearly additional studies are needed to elucidate how serotonin regulates cortical interneurons. One important question that will need to be addressed is whether serotonin regulates different interneuron types in a uniform manner across different layers and cortical regions. The growing availability of transgenic mice expressing fluorescent proteins in selected subpopulations of cells, including interneurons (Ma *et al.*, 2006), should greatly facilitate such studies.

### ***Serotonergic regulation of cortical synaptic plasticity***

In addition to regulating neuronal excitability, serotonin also plays an important role in regulating synaptic plasticity in cortex. Since synapses strengthen or weaken as a function of activity levels, serotonin-induced changes in cellular excitability alone can be expected to regulate synaptic plasticity. However, it is now widely believed that neurotransmitters acting via GPCRs, and serotonin in particular, may in fact have a much more pervasive effect, functioning as gatekeepers for synaptic plasticity – a process often called metaplasticity.

The visual cortex provides what is probably the clearest example of a serotonin regulation of synaptic plasticity. It has been known for many years that synaptic inputs to the visual cortex during development can express activity-dependent plasticity during a transient phase known

as the critical period. Work in the mid-1990s showed that at least some forms of synaptic plasticity expressed during this period were dependent on 5-HT<sub>2</sub> serotonin receptor activation (Gu and Singer, 1995; Kojic *et al.*, 1997). Subsequent work showed that expression of this serotonin-dependent synaptic plasticity coincided with the transient expression of 5-HT<sub>2</sub> receptor patches in visual cortex, and that activation of 5-HT<sub>2</sub> receptors facilitated the expression of long-term potentiation in neurons of layer IV (Kojic *et al.*, 2000, 2001). Interestingly, a recent study has reported that administration of fluoxetine to adult rats restores visual plasticity lost after the critical period, although the relationship of these observations to the earlier studies remains unspecified (Maya Vetencourt *et al.*, 2008). These limitations notwithstanding, the studies provide compelling support for the idea that serotonin could regulate synaptic plasticity in cortex.

These studies, while tantalizing, could not address potential cellular and molecular mechanisms underlying this phenomenon. A recent study from the Kirkwood laboratory (Seol *et al.*, 2007), however, while not directly addressing serotonergic mechanisms, has shown that neurotransmitter receptors coupling to G $\alpha_s$  and G $\alpha_{q-11}$  in the visual cortex promote long-term potentiation and long-term depression in pyramidal cells through the phosphorylation of glutamate receptors. These are exciting findings that link signaling steps downstream from GPCRs to our rapidly growing understanding of the molecular mechanisms underlying synaptic plasticity. However, it is noteworthy that the polarity of the 5-HT<sub>2</sub> receptor-mediated metaplasticity observed in the earlier studies in visual cortex are the reverse of those predicted by these more recent findings (Choi *et al.*, 2005; Seol *et al.*, 2007). This is a puzzling discrepancy that may reflect the significant experimental differences between the two sets of studies. In any case, direct support for the idea that G $\alpha_{q-11}$  coupled 5-HT<sub>2</sub> receptors may promote long-term depression in cerebral cortex has recently been obtained in prefrontal cortex (Zhong *et al.*, 2008), although the mechanism proposed to underlie this effect appears different from that expected from the work by the Kirkwood lab.

Clearly our understanding of the mechanism by which serotonin receptors regulate synaptic plasticity is in its early infancy. There are multiple forms of synaptic plasticity, both long-term potentiation and long-term depression, and it seems highly unlikely that different synapses in cortex would uniformly express a single type of either of these. Furthermore, different synapses in cortex may be differentially regulated by serotonin depending on the specific form(s) of synaptic plasticity they express and the serotonin receptor subtypes expressed in the presynaptic and postsynaptic elements. Given the technical difficulties inherent in

studying homogeneous populations of synapses in cortex, it will take clever, technically innovative approaches to address these issues.

### *Cortical serotonin during development*

The expression of serotonin receptor subtypes in the brain, and the cerebral cortex in particular, is under strong developmental control (see, for example, Beique *et al.*, 2004a; Bonnin *et al.*, 2006; Waeber *et al.*, 1994; Vizuete *et al.*, 1997). Changes in receptor expression levels appear particularly prominent during the prenatal and early postnatal periods, which represent key times for synaptogenesis and synaptic refinement (Zhang, 2006). Recent studies have shown that these changes in receptor levels can fundamentally reshape what serotonin does in the cerebral cortex (Zhang, 2003; Beique *et al.*, 2004a, 2004b). For example, during the early postnatal period, pyramidal cells of layer V of the prefrontal cortex are profoundly depolarized by serotonin, an effect that is mediated by the activation of 5-HT<sub>2A</sub> and also by 5-HT<sub>7</sub> receptors that are transiently expressed in this area at this age (Zhang, 2003; Beique *et al.*, 2004a). By the third postnatal week, however, 5-HT<sub>7</sub> receptors are no longer expressed on pyramidal cells of the prefrontal cortex, and 5-HT<sub>2A</sub> receptors have become largely uncoupled from the ion channels mediating the membrane depolarization (Beique *et al.*, 2004a). *Pari passu* with these changes, 5-HT<sub>1A</sub> receptors begin to appear, signaling the characteristic hyperpolarization that is the hallmark effect of these receptors in adult animals (Beique *et al.*, 2004a). These changes in excitability have been hypothesized to play a role in setting the rules for the synaptic refinement that takes place during this developmental epoch. However, how specifically these effects contribute to the refinement of prefrontal cortical circuits, if at all, remains to be determined.

Perhaps the best understood effect of serotonin on the development of cortical circuits is the 5-HT<sub>1B</sub> receptor modulation of the thalamic innervation of somatosensory cortex. 5-HT<sub>1B/D</sub> receptors are transiently expressed in the thalamic fibers innervating the barrel cortex, and either depletion of serotonin or inhibition of 5-HT<sub>1B/D</sub> receptor function results in impairment of the formation of vibrissae-related patches in layer IV (Young-Davies *et al.*, 2000, and references therein). The mechanism underlying this phenomenon remained mysterious for many years. However, recently Bonnin and associates, in a remarkable technical *tour de force*, have shown that serotonin acting on 5-HT<sub>1B/D</sub> receptors regulates the guidance clues transmitted through netrin-1 onto thalamocortical axons (Bonnin *et al.*, 2007). In the absence of serotonin, or

5-HT<sub>1B/D</sub> receptors, the resulting deficit in pathfinding is thought to account for the disruption of the sensory map.

### **The road ahead**

Over 25 years ago the authors of this review started to work on serotonin, fascinated by the possibility of making sense of its bewildering electrophysiology in central neurons through an understanding of serotonin receptor subtypes. Thanks to the work of many labs – many more than can be acknowledged here – a good portion of what we wanted to know, namely understanding what each receptor subtype signals in central neurons, has been clarified. Yet, as is patently clear in this chapter, this knowledge has proven grossly insufficient as a way to understand how serotonin regulates neuronal function in the brain.

A number of critical challenges remain. First, going in the systems neuroscience direction, it is now clear that, to understand what serotonin does, we need to understand what it does in the context of specific neuronal circuits. That is the fundamental message from this chapter. But beyond that, we need to understand how serotonin receptors are activated by both volume transmission and synaptically released serotonin under physiological conditions. For example, does a single serotonergic cell, or group of serotonergic neurons, control all the different serotonin receptors on a given postsynaptic neuron, or only some in specific locations, or some of a particular subtype? These, and many more similar questions, are critical to our understanding of the physiology of serotonin; yet at the present time we cannot provide answers.

Second, and now moving in the direction of cellular neuroscience, it is now clear that GPCRs do not signal solely via G proteins. Rather, they function as ligand-activated signaling platforms capable of involving a variety of molecular partners. This is likely to shape serotonergic signaling mediated through the G protein and to add additional complexities to what is being signaled. Integrating these advances in our understanding of serotonin receptors' function into the physiological context of central neurons is likely to consume the next 25 years and beyond.

### **Acknowledgements**

Work in the authors' laboratories has been supported by NIH grants MH43987 and the State of Michigan (to Rodrigo Andrade) and NIH grants MH075047, MH39004, MH63078 and NS28512 (to Sheryl G. Beck). The authors thank Dr Jerrel Yakel for the 5-HT<sub>3</sub> trace used in Figure 2.

# Serotonergic Feedback Control

Trevor Sharp\*

*University Department of Pharmacology, Oxford, UK*

**Abstract:** This chapter discusses current knowledge of the pharmacology and physiology of the feedback mechanisms that control serotonin (5-hydroxytryptamine; 5-HT) neurons, and considers their possible contribution to the pathophysiology and treatment of psychiatric disorders, especially major depression. A key mechanism involved in the control of 5-HT neurons is feedback inhibition by presynaptic 5-HT autoreceptors. These autoreceptors are implicated in depression and anxiety neurobiology, and form the basis of various ongoing 5-HT drug discovery efforts in these therapeutic areas. Recent experiments have discovered further complexity of 5-HT neuron control, specifically in the form of postsynaptic feedback mechanisms. These mechanisms have the physiological effects of 5-HT autoreceptors but use additional 5-HT receptor subtypes, and operate via neural inputs to 5-HT neurons. There is also recent evidence for postsynaptic feedback systems that excite 5-HT neurons. The postsynaptic feedback mechanisms are also providing a new source of drug targets for therapeutic application. Overall, current data suggest the presence of a previously unsuspected, complex arrangement of pre- and postsynaptic 5-HT receptor-mediated feedback mechanisms that control 5-HT neuron function.

**Keywords:** 5-HT autoreceptor, 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>2</sub>, 5-HT<sub>4</sub>, dorsal raphe nucleus, electrophysiology, depression, antidepressant.

## Introduction

Serotonin (5-hydroxytryptamine; 5-HT) is implicated in numerous important brain functions, ranging from regulation of circadian changes in the sleep–wake cycle to processing of complex information linked to emotion and cognition. Moreover, changes in 5-HT have been linked to both the pathophysiology and successful treatment of many common psychiatric disorders, including depression, anxiety and schizophrenia.

The 5-HT innervation of the forebrain derives from clusters of 5-HT neurons in the midbrain raphe nuclei, especially the dorsal raphe nucleus (DRN). Across a range of species, many (but not all) DRN 5-HT neurons are characterized by a spontaneous, slow and regular firing pattern (Allers and Sharp, 2003), suggesting the presence of strict feedback control mechanisms. This idea arose from earlier observations that 5-HT receptor agonists inhibited the firing of 5-HT neurons *in vivo* (Aghajanian *et al.*, 1972). In addition, application of 5-HT or 5-HT receptor agonists to *in vitro* brain preparations was found to inhibit the release of preloaded radiolabeled 5-HT (Farnebo and Hamberger,

1971; Gothert and Weinheimer, 1979). Together these findings suggested the presence of presynaptic ‘5-HT autoreceptors’ which acted at the somatodendrites and nerve terminals of 5-HT neurons to inhibit transmission. Subsequent pharmacological and genetic analysis of these effects, combined with new information on the diversity of 5-HT receptor subtypes and their cellular localization, led to the current 5-HT autoreceptor model which invokes a key role for the 5-HT<sub>1</sub> receptor family.

## 5-HT autoreceptors

The current 5-HT autoreceptor model proposes a population of 5-HT autoreceptors (5-HT<sub>1A</sub>) located on the soma and dendrites of 5-HT neurons which open potassium channels (and possibly reduce Ca<sup>2+</sup> conductance) via G-protein coupling to inhibit 5-HT cell firing (Innis *et al.*, 1988; Barnes and Sharp, 1999). Another population of 5-HT autoreceptors (5-HT<sub>1B</sub>) is located on nerve terminals which G-protein couple to inhibit adenylate cyclase and/or open potassium channels to directly inhibit 5-HT release (Middlemiss and Hutson, 1990; Barnes and Sharp, 1999). The presence of additional populations of 5-HT autoreceptors (5-HT<sub>1D</sub> and 5-HT<sub>5A</sub>), which modulate 5-HT release at the level of the soma, dendrites and possibly

\*E-mail: trevor.sharp@pharm.ox.ac.uk

nerve terminals, is also proposed (Piñeyro *et al.*, 1995a; Stamford *et al.*, 2000; Thomas *et al.*, 2006).

### **5-HT<sub>1A</sub> autoreceptors**

*In vivo* electrophysiological studies in the 1970s found that systemically and locally applied LSD inhibited 5-HT cell firing in the rat DRN (Aghajanian *et al.*, 1972; Haigler and Aghajanian, 1974). Subsequent detailed pharmacological analysis of this phenomenon identified the role of 5-HT<sub>1A</sub> receptors. For example, electrophysiological studies found that a wide range of 5-HT<sub>1A</sub> receptor agonists (including 8-OH-DPAT) had the same effect, and that this action was blocked by non-selective (spiperone) and selective (WAY 100635) 5-HT<sub>1A</sub> receptor antagonists (Sprouse and Aghajanian, 1988; Craven *et al.*, 1994; Corradetti *et al.*, 1996). Partial 5-HT<sub>1A</sub> agonists such as NAN-190 and SDZ 216,525 were also found to inhibit 5-HT cell firing via 5-HT<sub>1A</sub> receptor activation (Lanfumeey *et al.*, 1993; Fornal *et al.*, 1994).

These electrophysiological data were strongly supported by findings from *in vivo* microdialysis measurements of extracellular 5-HT. For example, such studies demonstrated that administration of 5-HT<sub>1A</sub> agonists (8-OH-DPAT) or partial agonists (e.g., NAN-190, SDZ 216,525) decreased extracellular 5-HT in rat forebrain regions via 5-HT<sub>1A</sub> receptor activation (Sharp *et al.*, 1989a, 1996; Sharp and Hjorth, 1990). More recent electrophysiological and microdialysis experiments using 5-HT<sub>1A</sub> knockout mice confirm the pharmacological identity of the 5-HT<sub>1A</sub> autoreceptor (Knobelman *et al.*, 2001; Gross *et al.*, 2002; Guilloux *et al.*, 2006).

Curiously, the non-selective 5-HT receptor antagonists methiothepin, metergoline and methysergide were found to inhibit 5-HT cell firing (Haigler and Aghajanian, 1974) and release (Sharp *et al.*, 1989b), which may be due to 5-HT<sub>1A</sub> receptor activation, although  $\alpha_1$ -adrenoceptor or indeed partial 5-HT<sub>2</sub> receptor agonist activity may be contributing factors (see later). In fact, it was only very recently that the inhibitory effect of LSD on 5-HT cell firing was shown to be mediated by 5-HT<sub>1A</sub> receptors and not other 5-HT receptor subtypes subsequently found to inhibit 5-HT cell firing (Quéree *et al.*, 2009).

Findings regarding 5-HT<sub>1A</sub> receptor localization support electrophysiological evidence for the presence of 5-HT<sub>1A</sub> receptors on midbrain 5-HT neurons. For example, radioligand binding and immunocytochemical studies in rodent and human tissue demonstrated the presence of high densities of 5-HT<sub>1A</sub> receptors localized in the DRN (Verge *et al.*, 1986; Sotelo *et al.*, 1990; Castro *et al.*, 2000). Moreover, 5-HT<sub>1A</sub> receptor immunolabeling coexisted with 5-HT neuron markers, and 5-HT<sub>1A</sub> binding sites and mRNA in the DRN were diminished by 5-HT neuron lesions (Miquel *et al.*, 1992; Radja *et al.*, 1992; Kia *et al.*, 1996).

Although the inhibition of 5-HT cell firing *in vivo* by 5-HT<sub>1A</sub> agonist administration was thought to be mediated via 5-HT<sub>1A</sub> receptors located on midbrain 5-HT neurons, subsequent data raised the possibility of a contribution from postsynaptic 5-HT<sub>1A</sub> receptors in the forebrain (see later).

### **5-HT<sub>1B</sub> autoreceptors**

There is convincing evidence that the 5-HT<sub>1B</sub> receptor functions as a 5-HT autoreceptor at the nerve terminal. For example, *in vitro* brain slice studies demonstrate a strong correlation between the potency with which 5-HT receptor agonists and antagonists inhibit and enhance (respectively) release of preloaded radiolabeled 5-HT, and their affinity for the rat 5-HT<sub>1B</sub> binding site (Middlemiss, 1984; Engel *et al.*, 1986; Limberger *et al.*, 1991; Buhlen *et al.*, 1996). Work using the same model demonstrated the presence of the 5-HT<sub>1B</sub> autoreceptor (5-HT<sub>1DB</sub> in old nomenclature) in human brain (Galzin *et al.*, 1992; Maura *et al.*, 1993; Schlicker *et al.*, 1997). Such *in vitro* findings are supported by the effects of selective 5-HT<sub>1B</sub> receptor agonists and antagonists on extracellular 5-HT in brain microdialysis studies (Sharp *et al.*, 1989a; Hjorth and Tao, 1991; Knobelman *et al.*, 2000). Moreover, both *in vivo* microdialysis (Trillat *et al.*, 1997; Knobelman *et al.*, 2001) and *in vitro* brain slice studies (Piñeyro *et al.*, 1995a; Rutz *et al.*, 2006) demonstrated that 5-HT<sub>1B</sub> receptor agonists do not inhibit the release of 5-HT in 5-HT<sub>1B</sub> receptor knockout mice. While the latter studies tend to rule out a significant role for the 5-HT<sub>1D</sub> receptor in feedback control, *in vitro* data suggest that 5-HT<sub>1D</sub> receptors inhibit 5-HT efflux specifically in the DRN (Piñeyro *et al.*, 1995b; Stamford *et al.*, 2000). However, the precise molecular and cellular basis of this mechanism remains obscure.

Findings on 5-HT<sub>1B</sub> receptor localization are fully consistent with a nerve terminal 5-HT<sub>1B</sub> autoreceptor (Sari, 2004). Specifically, in the midbrain raphe nuclei 5-HT<sub>1B</sub> receptor mRNA is present in 5-HT cell bodies (Doucet *et al.*, 1995), and much evidence suggests that 5-HT<sub>1B</sub> receptor protein is synthesized at the soma and then transported to the nerve terminals. For example, studies using cell cultures transfected with 5-HT<sub>1B</sub> receptor constructs demonstrated that the protein is preferentially addressed away from the soma to axons (Darmon *et al.*, 1998; Ghavami *et al.*, 1999). Moreover, ultra-structural studies found that 5-HT nerve terminals autographically labeled with radioactive 5-HT, co-localize 5-HT<sub>1B</sub> receptor immunoreactivity (Sari, 2004).

### **Antidepressant augmentation using 5-HT autoreceptor antagonists**

A shortcoming of even the most modern antidepressants including selective 5-HT (serotonin) reuptake inhibitors

(SSRIs) is that they are slow to act, often poorly tolerated, and fail to produce a satisfactory response in a high proportion (> 30 percent) of patients (Artigas *et al.*, 2006). Current pharmacological strategies aimed to augment the therapeutic effect of SSRIs include combination with a 5-HT<sub>1</sub> autoreceptor antagonist.

The rationale for these strategies is evidence that when administered acutely, SSRIs indirectly activate 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> autoreceptors, which limits the ability of these drugs to enhance 5-HT transmission. Evidence suggests that 5-HT autoreceptors desensitize after a course (weeks) of SSRI treatment (Blier *et al.*, 1988; Blier and Bouchard, 1994; Newman *et al.*, 2004) leading to an increase in 5-HT function, which triggers the critical downstream events (e.g., increase synaptic plasticity, etc.) that are thought to underpin the relief of depression. The idea is that the use of autoreceptor antagonists would circumvent the delay in time needed for the desensitization process to come about.

In support of this thinking, 5-HT<sub>1A</sub> receptor antagonists were shown to prevent the inhibitory effect of the SSRIs on 5-HT cell firing in different species (Gartside *et al.*, 1995; Bjorvatn *et al.*, 2000). Moreover, 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor antagonists were found to augment the effect of SSRIs on 5-HT function. For instance, microdialysis studies showed that 5-HT<sub>1A</sub> receptor antagonists facilitated the effect of SSRIs (as well as monoamine oxidase inhibitors and certain tricyclic antidepressants) on extracellular 5-HT (Gartside *et al.*, 1995; Gobert *et al.*, 1997; Invernizzi *et al.*, 1997). Also, 5-HT<sub>1B</sub> antagonists augmented SSRI effects in some (but not all) microdialysis experiments (Rollema *et al.*, 1996; Gobert *et al.*, 1997), and potentiated the effects of SSRI/5-HT<sub>1A</sub> receptor antagonist combinations (Gobert *et al.*, 1997; Sharp *et al.*, 1997; Dawson and Nguyen, 2000). More recently, co-administration of a 5-HT<sub>1A</sub> receptor antagonist with a SSRI resulted in enhanced responses in some behavioral models (e.g., Duxon *et al.*, 2000; Muraki *et al.*, 2008) but not in others (Cryan *et al.*, 1999), and enhanced 5-HT mediated expression of activity-dependent genes (Castro *et al.*, 2003; Tordera *et al.*, 2003).

Such studies have lead to the clinical investigation of the utility of the non-selective 5-HT<sub>1A</sub> ligand pindolol as an SSRI augmenting agent. Some trials found that pindolol/SSRI combinations were beneficial, but data are complicated by a number of issues, including differences in the demographic characteristics of the patients studied (Ballesteros and Callado, 2004; Segrave and Nathan, 2005). A recent meta-analysis of 11 randomized trials showed a greater response with pindolol augmentation versus placebo and an overall beneficial clinical effect, most clearly up to 4 weeks of treatment (Whale *et al.*, 2008). Unfortunately, the progression of such studies is hampered by the non-selectivity and partial agonist

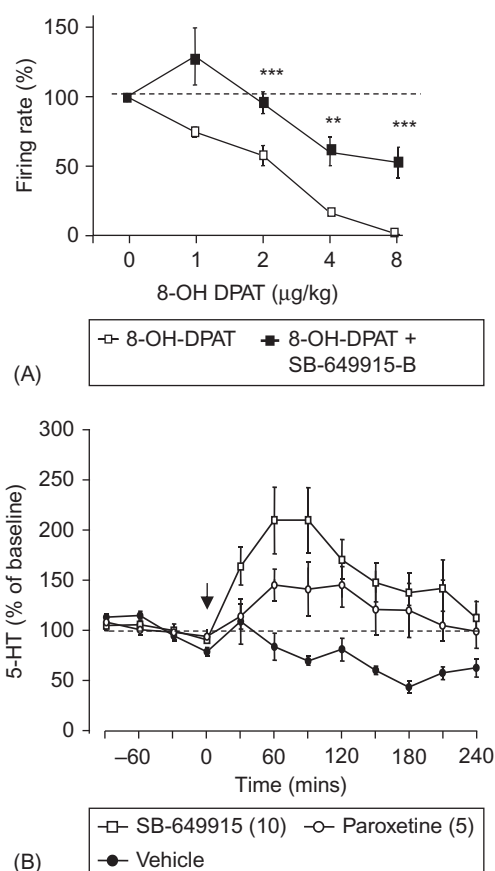

properties of pindolol (Clifford *et al.*, 1998), and the difficulty of finding a tolerable dose that achieves high levels of 5-HT<sub>1A</sub> receptor occupancy (Rabiner *et al.*, 2000).

Current research is focused on the development of selective 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor antagonists and inverse agonists, and 'dual' and 'triple' action drugs which have combined 5-HT transporter/5-HT<sub>1A</sub>/5-HT<sub>1B</sub> blocking properties (Millan, 2009). Preliminary data on a number of 'dual-activity' 5-HT transporter/5-HT<sub>1A</sub> receptor ligands have been reported, including vilazodone (Heinrich *et al.*, 2004; Hughes *et al.*, 2005), VN2222 (Romero *et al.*, 2003), BMS-296859 (Taber *et al.*, 2003), WAY-163426 (Hornby *et al.*, 2004), Lu 36-274 (Mørk and Hogg, 2003) and 4-aryl-pyrido[1,2-c]pyrimidine (Herold *et al.*, 2009). Whilst analysis of the actions of these agents remains incomplete, both vilazodone and VN2222 appear to demonstrate evidence of partial 5-HT<sub>1A</sub> agonist properties. Recently, data on the first reported triple action SSRI/5-HT<sub>1A</sub>/5-HT<sub>1B</sub> antagonist, SB-649915-B were described (Hughes *et al.*, 2007). In electrophysiological and microdialysis experiments, SB-649915 did not alter 5-HT cell firing *per se* but blocked the inhibitory effect of 8-OH-DPAT, and caused a greater increase of extracellular 5-HT in rat cortex than an SSRI (Figure 1). Importantly, in an anxiety model SB-649915 was anxiolytic, with a faster onset of effect compared to an SSRI (Starr *et al.*, 2007). Clearly, it is of great interest to see how drugs of this class fare in clinical trials.

### ***Physiological and pathophysiological effects of 5-HT autoreceptors***

Earlier studies using animal models link the decrease in 5-HT transmission evoked by 5-HT<sub>1</sub> autoreceptor activation to a range of behavioral and physiological effects, including anxiolysis, hypolocomotion, hyperphagia, and hypothermia (De Vry, 1995; Barnes and Sharp, 1999). More recently, 5-HT<sub>1</sub> autoreceptor activation and the consequent inhibition of 5-HT cell firing and release has been associated with reduced aggression (de Boer and Koolhaas, 2005) and enhancement of psychostimulant-induced hyperactivity and sensitization (Carey *et al.*, 2008).

5-HT<sub>1</sub> autoreceptors are implicated in both the cause and treatment of a variety of psychiatric illnesses, but in particular depression and other stress-related disorders. For example, abnormal 5-HT<sub>1A</sub> autoreceptor function and consequent changes in 5-HT release are thought to contribute to maladaptive responses to stress in animal models of depression as well as patients with unipolar or bipolar depression (Lanfumey *et al.*, 1999; Lesch and Gutknecht, 2004; Cowen, 2008; Sullivan *et al.*, 2009). Moreover, in human volunteers, natural variation in

**Figure 1** Effects of the SSRI/5-HT<sub>1A</sub>/5-HT<sub>1B</sub> receptor antagonist SB-649915-B on (A) 5-HT cell firing in the DRN and (B) cortical extracellular 5-HT, in the rat. In (A), note the blockade of the inhibitory effect of the 5-HT<sub>1A</sub> agonist 8-OH-DPAT by SB-649915-B (3 mg/kg i.v.). \*\* $P < 0.01$ , \*\*\* $P < 0.001$  versus vehicle. In (B), both the SSRI paroxetine and SB-649915-B have a significant effect of 5-HT compared to controls (doses are in mg/kg as indicated). Data taken in part from Hughes *et al.* (2007). Mean  $\pm$  SEM values shown ( $n = 6-8$  per group).

levels of 5-HT<sub>1A</sub> autoreceptor density, possibly due to polymorphic variation in the 5-HT<sub>1A</sub> receptor gene, have been associated with neuroimaging correlates of anxiety (Fisher *et al.*, 2006; Fakra *et al.*, 2009).

In an exciting recent development, altered 5-HT homeostasis brought about through abnormalities in 5-HT<sub>1A</sub> autoreceptor have been linked to the catastrophic autonomic sequelae underlying sudden infant death (Audero *et al.*, 2008). Specifically, it was found that mice over-expressing the 5-HT<sub>1A</sub> autoreceptor died early in life due to failure of necessary autonomic changes likely to compensate for changes in environment and stress.

Given that 5-HT<sub>1A</sub> receptor activation has such powerful effects on 5-HT transmission, and the above evidence that changes in 5-HT<sub>1A</sub> autoreceptor function can have

important pathophysiological outcomes, it is surprising that evidence for the presence of 5-HT<sub>1A</sub> autoreceptor tone in *in vivo* models is controversial. For example, reports on the effects of 5-HT<sub>1A</sub> receptor antagonists administered systemically alone on 5-HT cell firing *in vivo* are inconsistent, although slight increases have been detected in anesthetized animals in some studies (Gartside *et al.*, 1995; Hajós *et al.*, 2001). Similarly, in *in vivo* microdialysis studies, neither selective 5-HT<sub>1A</sub> nor 5-HT<sub>1B</sub> receptor antagonists by themselves consistently increased extracellular 5-HT in brain regions of either anesthetized or awake animals (Gobert *et al.*, 1997; Sharp *et al.*, 1997). In support of these findings, it is reported that brain extracellular levels of 5-HT in brain regions of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor knockout mice are not different from those in wild-type controls (He *et al.*, 2001; Gardier *et al.*, 2003; Guilloux *et al.*, 2006).

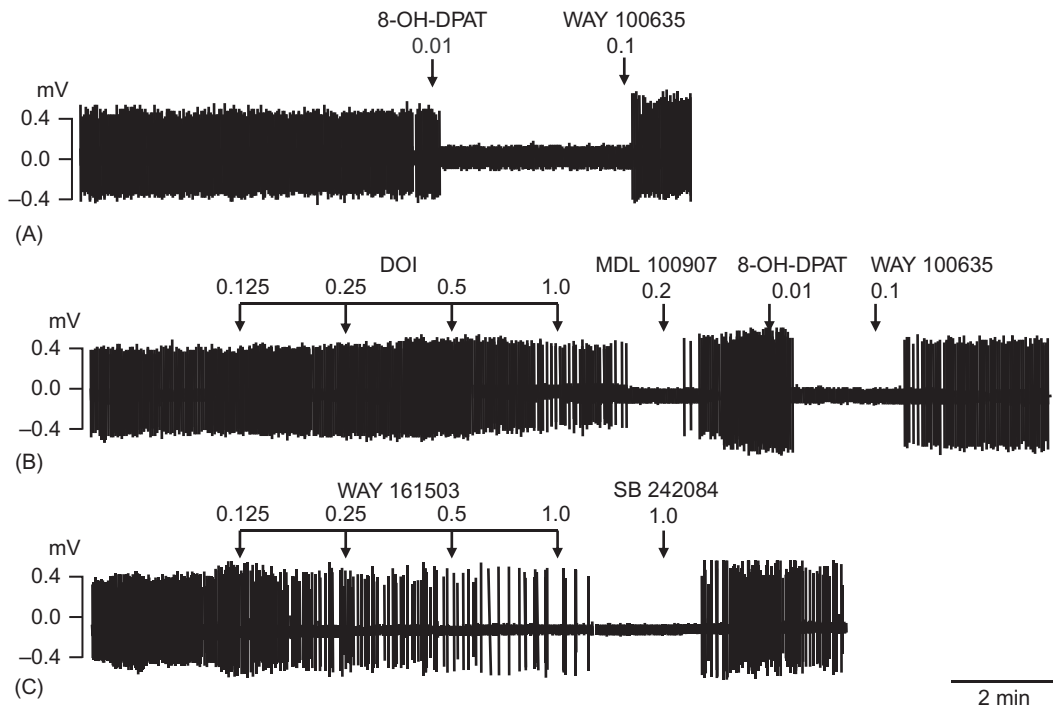

This said, the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 had a clear-cut stimulatory effect on 5-HT cell firing in cats in the active-awake state (Fornal *et al.*, 1996). Moreover, the latter drug also increased 5-HT cell firing in anesthetized rats with noradrenaline depletions, suggesting that 5-HT tone at the 5-HT<sub>1A</sub> autoreceptor may be masked by modulatory influences of noradrenaline (Haddjeri *et al.*, 2004). Thus, these data can be taken as evidence that 5-HT<sub>1A</sub> autoreceptors are under strong physiological tone *in vivo*, at least in some conditions.

## Postsynaptic 5-HT feedback control mechanisms

Whilst the importance of 5-HT<sub>1</sub> autoreceptors is clear, emerging findings indicate additional complexity of 5-HT feedback control, specifically in the form of feedback mechanisms involving postsynaptic 5-HT receptors (i.e., 5-HT receptors located on non-5-HT neurons). This idea derives in part from *in vivo* electrophysiological studies showing that not only 5-HT<sub>1A</sub> receptor agonists but also agonists for a range of other 5-HT receptor subtypes alter 5-HT cell firing and release (Figure 2; Table 1).

### Feedback involving postsynaptic 5-HT<sub>1A</sub> receptors

Evidence from animal studies indicates that 5-HT<sub>1A</sub> receptor agonist-induced inhibition of 5-HT cell firing can be dissociated from an action on somatodendritic 5-HT<sub>1A</sub> autoreceptors. For example, transection of the rostral forebrain attenuated the inhibition of 5-HT cell firing induced by (systemically administered) 5-HT<sub>1A</sub> receptor agonists even though the sensitivity of somatodendritic 5-HT<sub>1A</sub> receptors in the DRN was not changed (Ceci *et al.*, 1994; Hajós *et al.*, 1999). Also, local injection of a

**Figure 2** Electrophysiological evidence for the presence of 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> feedback control of midbrain 5-HT neurons. Traces are spike trains from recordings of individual 5-HT neurons in the DRN of anesthetized rats, injected systemically with specific 5-HT receptor agonists. (A) Inhibitory effect of the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT and reversal by the 5-HT<sub>1A</sub> receptor antagonist WAY 100635. (B) Inhibitory effect of the 5-HT<sub>2</sub> receptor agonist DOI and reversal by the 5-HT<sub>2A</sub> receptor antagonist MDL 100907. Note that the same neuron is also inhibited by 8-OH-DPAT, providing evidence for control of this neuron by both 5-HT<sub>2A</sub> and 5-HT<sub>1A</sub> receptors. (C) Inhibitory effect of the 5-HT<sub>2C</sub> receptor agonist WAY 161503 and reversal by the 5-HT<sub>2C</sub> receptor antagonist SB 242084. Drug administration (mg/kg i.v.) as indicated by arrows.

5-HT<sub>1A</sub> receptor agonist into regions outside of the DRN decreased 5-HT cell firing and 5-HT release (Hajós *et al.*, 1999; Celada *et al.*, 2001). Importantly, 5-HT<sub>1A</sub> agonist-induced inhibition of 5-HT cell firing and release were not markedly influenced by localized pharmacological blockade or inactivation of 5-HT<sub>1A</sub> receptors in the DRN (Romero *et al.*, 1994; Martín-Ruiz and Ugedo, 2001). Collectively, these findings suggest that a population of 5-HT<sub>1A</sub> receptors outside the DRN contributes to 5-HT<sub>1A</sub> agonist-induced inhibition of 5-HT cell firing and release – i.e., that both pre- and postsynaptic 5-HT<sub>1A</sub> receptors are involved.

#### Feedback involving postsynaptic 5-HT<sub>2</sub> receptors

Accumulating evidence suggests that postsynaptic 5-HT<sub>2</sub> receptors also regulate 5-HT cell firing. In particular, when administered systemically, phenethylamine derivatives, such as DOM (1-(2,5-di-methoxy-4-methylphenyl)-2-aminopropane) and DOI (2,5-dimethoxy-4-iodo-amphetamine), which have 5-HT<sub>2</sub> agonist properties in a range of models (Barnes and Sharp, 1999), decreased both 5-HT cell fir-

ing and brain extracellular 5-HT (Wright *et al.*, 1990; Boothman *et al.*, 2003). Recent experiments confirm the involvement of 5-HT<sub>2</sub> receptors in these effects. For example, the inhibition of 5-HT cell firing induced by DOI was blocked by the 5-HT<sub>2</sub> receptor antagonist, ritanserin, as well as the 5-HT<sub>2A</sub> receptor antagonist MDL 100907, suggesting the involvement of the 5-HT<sub>2A</sub> receptor subtype (Figure 2; Martín-Ruiz *et al.*, 2001; Boothman *et al.*, 2003).

Interestingly, the 5-HT<sub>2B/C</sub> receptor antagonist SB 206553 partially attenuated DOI-induced inhibition of 5-HT cell firing (Boothman *et al.*, 2003), implicating a role for 5-HT<sub>2B/C</sub> receptors. This was confirmed by recent studies demonstrating that the putative 5-HT<sub>2C</sub> receptor agonists WAY 161503, Ro 600175 and mCPP inhibited 5-HT cell firing, and in each case the effect was reversed by the selective 5-HT<sub>2C</sub> receptor antagonist SB 242084 (Boothman *et al.*, 2006b; Quéree and Sharp, 2006; Quéree *et al.*, 2009).

Collectively, these data support a role for both 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptor subtypes in the inhibitory feedback control of 5-HT cell firing. Since neither 5-HT<sub>2A</sub> nor 5-HT<sub>2C</sub> receptors are expressed by 5-HT neurons

**Table 1** Some evidence implicating specific postsynaptic 5-HT receptor subtypes in the feedback control of midbrain 5-HT neurons

5-HT receptor subtype	Evidence	Comment	Reference
5-HT <sub>1A</sub>	See main text		
5-HT <sub>1B</sub>	Systemic administration of 5-HT <sub>1B</sub> agonists (RU 24969, CP 94253) increases the firing of 5-HT neurons in rat DRN <i>in vivo</i> .	Effect blocked by 5-HT <sub>1B</sub> antagonist (GR 127935). Data do not exclude 'disinhibition' of 5-HT neurones through activation of presynaptic 5HT <sub>1B</sub> autoreceptor. 5-HT <sub>3</sub>	Local application of 5-HT <sub>3</sub> agonists (2-methyl-5-HT) increased 5-HT efflux in rat and guinea pig brain regions (hippocampus, cortex) <i>in vitro</i> and <i>in vivo</i> .	Effect blocked by 5-HT <sub>3</sub> antagonist (e.g. MDL 72222).	
5-HT <sub>4</sub>	See main text		
5-HT <sub>5A</sub>	Local application of a 5-HT <sub>5A</sub> antagonist (SB-699551-A) attenuated the 5-CT-induced depression in 5-HT cell firing in guinea pig DRN <i>in vitro</i> .	Effect may be mediated by 5-HT <sub>5A</sub> receptors located presynaptically on 5-HT neurons.	Thomas <i>et al.</i> , 2005
5-HT <sub>6</sub>	Systemic administration of 5-HT <sub>6</sub> agonist (WAY-181187) decreased 5-HT efflux in rat cortex <i>in vivo</i> .	Effect blocked by 5-HT <sub>6</sub> antagonist (SB-271046). Effect region-specific (cortex but not 5 other regions).	Schechter <i>et al.</i> , 2008
5-HT <sub>7</sub>	Local application of 5-HT <sub>7</sub> antagonist (SB269970-A) inhibited 5-HT efflux in guinea pig DRN <i>in vitro</i> .		Roberts <i>et al.</i> , 2004

(Pazos *et al.*, 1985; Cornea-Hebert *et al.*, 1999), this form of feedback control likely involves postsynaptic mechanisms.

### Postsynaptic feedback – beyond 5-HT<sub>1A</sub> and 5-HT<sub>2</sub> receptor subtypes

In addition to 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors, other 5-HT receptor subtypes are implicated in postsynaptic 5-HT feedback control, and these include 5-HT<sub>3</sub>, 5-HT<sub>4</sub>, 5-HT<sub>5A</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub> (Table 1). The most investigated candidate is the 5-HT<sub>4</sub> receptor, which, interestingly, may mediate positive feedback control of 5-HT neurons. Specifically, Debonnel and colleagues (Lucas and Debonnel, 2002; Lucas *et al.*, 2005) reported that systemic administration of various 5-HT<sub>4</sub> receptor agonists, including RS 67333, increased 5-HT cell firing in the rat DRN. Moreover, this effect was attenuated by the 5-HT<sub>4</sub> receptor antagonist GR 125487, which by itself decreased 5-HT cell firing (Lucas and Debonnel, 2002). In keeping with these data, basal DRN 5-HT cell firing was reduced in 5-HT<sub>4</sub> receptor knockout mice, and increased in mice with virally-induced forebrain 5-HT<sub>4</sub> receptor overexpression (Lucas *et al.*, 2005; Conductier *et al.*, 2006).

These electrophysiological data accord with earlier microdialysis experiments (Ge and Barnes, 1996) showing that 5-HT<sub>4</sub> receptor agonists increased, whereas 5-HT<sub>4</sub> receptor antagonists decreased, extracellular 5-HT in rat hippocampus. Collectively, these data suggest that 5-HT<sub>4</sub> receptors exert a tonic, excitatory effect on 5-HT cell firing and release. This effect is likely mediated by 5-HT<sub>4</sub> receptors located postsynaptically, since 5-HT<sub>4</sub> receptors are abundant in the forebrain but lack measurable expression in the midbrain (Waeber *et al.*, 1994; Vilario *et al.*, 1996).

### Neural pathways involved in postsynaptic 5-HT feedback

The neural substrates of postsynaptic 5-HT feedback mechanisms are likely to lie amongst the many inputs to midbrain 5-HT neurons. Inputs that are already emerging as important include projections from the medial prefrontal cortex (mPFC) and lateral habenula nucleus (LHb) to the DRN, as well as DRN GABA neurons.

The mPFC–raphe pathway comprises a cortical glutamate projection that preferentially targets DRN GABA neurons to inhibit 5-HT cell firing (Hajós *et al.*, 1998; Varga *et al.*, 2001; Jankowski and Sesack, 2004). A minor glutamate projection from the mPFC that directly excites 5-HT cell firing in the DRN is also reported (Hajós *et al.*,

1998; Jankowski and Sesack, 2004). The LHb–DRN pathway also comprises an excitatory (principally glutamate) projection that targets DRN GABA neurons but there is also evidence of a direct inhibitory LHb–raphe GABA projection (Ferraro *et al.*, 1996; Varga *et al.*, 2003).

Electrophysiological data suggest that both mPFC–DRN and LHb–DRN projections influence large numbers of 5-HT neurons, probably through targeting the extensive network of GABA neurons in the DRN (Hajós *et al.*, 1998; Varga *et al.*, 2003). Indeed, morphological analysis of juxtacellular-labeled, single DRN GABA neurons revealed dendrites and varicose axon collaterals that spanned across DRN sub-regions and even across the midline to the contralateral side, suggesting an interaction with potentially large parts of the DRN 5-HT system (Allers and Sharp, 2003).

#### *mPFC–DRN pathways and postsynaptic 5-HT feedback*

The mPFC–DRN pathway is a putative neural substrate of postsynaptic 5-HT<sub>1A</sub> receptor feedback. The mPFC is rich in 5-HT<sub>1A</sub> receptors, and local application of 5-HT<sub>1A</sub> receptor agonists into this region decreased 5-HT cell firing in the DRN (Hajós *et al.*, 1999). Also, either lesion of the mPFC or intra-mPFC administration of a 5-HT<sub>1A</sub> receptor antagonist attenuated the inhibition of 5-HT cell firing and/or release induced by systemic 5-HT<sub>1A</sub> receptor agonist administration (Casanovas *et al.*, 1999; Hajós *et al.*, 1999). In support of these findings, 5-HT<sub>1A</sub> receptor agonists increased mPFC and DRN GABA neuron activity in electrophysiological and *c-fos* (a molecular marker of neural activity) studies (Borsini *et al.*, 1995; Hajós *et al.*, 1999; Raley *et al.*, 2004). Although 5-HT<sub>1A</sub> receptors are inhibitory, it is possible that activation of 5-HT<sub>1A</sub> receptors present on GABA interneurons in the mPFC (Aznar *et al.*, 2003; Santana *et al.*, 2004) results in disinhibition of the output glutamate neurons. Therefore, a potential scenario is that 5-HT<sub>1A</sub> receptors in the mPFC excite the mPFC–raphe glutamate projection to activate DRN GABA neurons, which then inhibit 5-HT cell firing (Figure 3).

Interestingly, the mPFC–DRN pathway is a putative substrate of 5-HT<sub>2A</sub> receptor feedback. For instance, the mPFC is rich in (excitatory) 5-HT<sub>2A</sub> receptors located on glutamate neurons (Cornea-Hebert *et al.*, 1999), and *c-fos* expression studies demonstrate that 5-HT<sub>2A</sub> receptor-mediated activation of both mPFC neurons (Raley *et al.*, 2004; Boothman and Sharp, 2005) and excitotoxic lesions of the mPFC attenuate the inhibitory effect of DOI on 5-HT cell firing (this laboratory, in preparation). DOI also evoked a 5-HT<sub>2A</sub> receptor-mediated increase in *c-fos* expression in DRN GABA neurons (Boothman and Sharp,

2005). Thus, 5-HT<sub>2A</sub> receptor activation may stimulate the mPFC–raphe glutamate projection to excite DRN GABA neurons, which then inhibit 5-HT cell firing (Figure 4).

Interestingly, evidence indicates that postsynaptic 5-HT<sub>4</sub> receptor feedback may also operate via the mPFC–DRN projection. Specifically, intra-mPFC injection of a viral construct designed to over-express 5-HT<sub>4</sub> receptors increased 5-HT cell firing in the DRN (Lucas *et al.*, 2005). Thus, activation of (excitatory) 5-HT<sub>4</sub> receptors in the mPFC may stimulate the excitatory mPFC–DRN projection to directly excite 5-HT neurons (Figure 3).

#### *LHb–DRN pathways and postsynaptic 5-HT feedback*

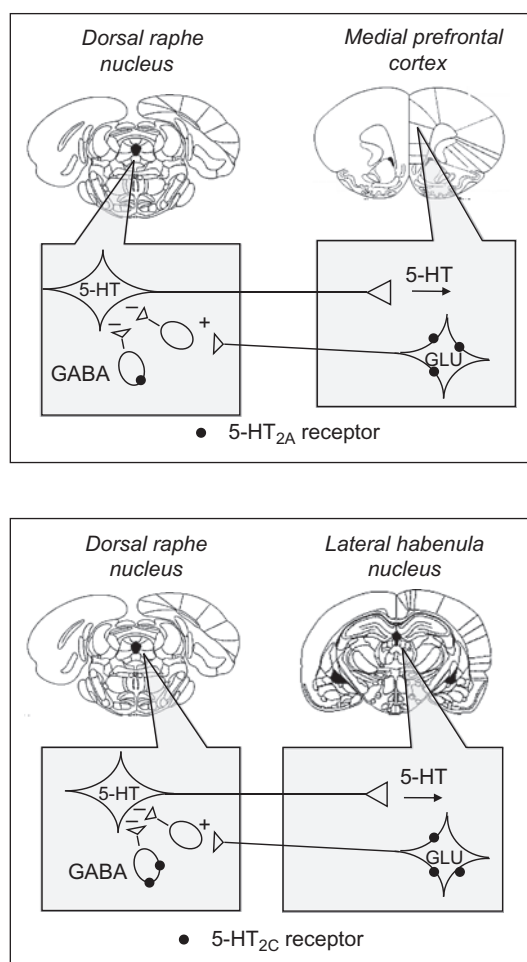

The LHb–DRN rather than the mPFC–DRN pathway is a putative substrate of the 5-HT<sub>2C</sub> feedback mechanism. The LHb is abundant in 5-HT<sub>2C</sub> receptor mRNA

**Figure 3** Diagram illustrating the theoretical neural pathways underlying feedback control of midbrain 5-HT neurons by postsynaptic 5-HT<sub>1A</sub> and 5-HT<sub>4</sub> receptors located on non-5-HT neurons in the mPFC. See text for details.

(Pompeiano *et al.*, 1994), and systemic administration of 5-HT<sub>2C</sub> receptor agonists including WAY 161503 elicited a striking, 5-HT<sub>2C</sub> receptor-mediated increase in *c-fos* expression in the LHb (Quéree *et al.*, unpublished data). 5-HT<sub>2C</sub> receptor agonist administration also increased *c-fos* expression in DRN GABA neurons (Boothman *et al.*, 2006b; Quéree *et al.*, 2009). Importantly, in preliminary experiments, excitotoxic lesions of the LHb markedly reduce 5-HT<sub>2C</sub> agonist-induced inhibition of 5-HT cell firing (Quéree *et al.*, unpublished observation). Thus, 5-HT<sub>2C</sub> receptor stimulation in the LHb may activate the LHb–DRN pathway to trigger the activity of DRN GABA neurons, which inhibits the firing of 5-HT neurons (Figure 4).

**Figure 4** Diagram illustrating the theoretical neural pathways underlying feedback control of midbrain 5-HT neurons by postsynaptic 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors located on non-5-HT neurons in the mPFC or LHb. See text for details.

### DRN GABA neurons and postsynaptic 5-HT feedback

DRN GABA neurons themselves may form a local postsynaptic feedback circuit that inhibits the firing of neighboring 5-HT neurons. Anatomical studies demonstrate reciprocal synaptic interactions between 5-HT and GABA neurons in the DRN, and in *in vitro* electrophysiological locally applied 5-HT evoked GABA-mediated inhibitory currents in DRN 5-HT neurons, this effect involving both 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptor subtypes (Liu *et al.*, 2000). In accord with these data, 5-HT<sub>2</sub> receptor agonist administration evoked a 5-HT<sub>2A</sub> receptor-mediated increase in *c-fos* expression in DRN GABA neurons (Figure 5; Boothman and Sharp, 2005; Boothman *et al.*, 2006b), and 5-HT<sub>2C</sub> receptor agonists have a similar effect (Boothman *et al.*, 2006b; Quéree *et al.*, 2009). Whilst activated mPFC/LHb inputs might contribute to the latter effects, both 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors directly activate DRN GABA neurons *in vitro* (Liu *et al.*, 2000), and immunocytochemical data suggest that DRN GABA neurons express 5-HT<sub>2C</sub> receptors (Serrats *et al.*, 2005; Boothman *et al.*, 2006b).

### Possible physiological roles of postsynaptic 5-HT feedback

To date, the evidence for the presence of postsynaptic 5-HT feedback derives largely from the use of 5-HT agonist probes, and it is not known whether these systems have important roles in physiology and pathophysiology, and if so which roles they play. It certainly appears to be the case that postsynaptic 5-HT feedback control is a common property of 5-HT neurons. In recent studies, almost all 5-HT neurons tested were responsive to 5-HT<sub>2A/C</sub> receptor agonist administration (Boothman *et al.*, 2003; Boothman *et al.*, 2006b). Also, 5-HT<sub>4</sub> receptor agonists were found to increase the firing rate in approximately 50 percent of DRN 5-HT neurons examined (Lucas and Debonnel, 2002), which is similar to the estimated number of DRN 5-HT neurons subject to feedback control by postsynaptic 5-HT<sub>1A</sub> receptors (Martín-Ruiz and Ugedo, 2001). Thus, significant numbers of 5-HT neurons appear responsive to postsynaptic feedback control. Moreover, since numerous individual 5-HT neurons were found to respond to both 5-HT<sub>1A</sub> and 5-HT<sub>2A/C</sub> receptor agonists (Boothman *et al.*, 2003; Boothman *et al.*, 2006b), it is likely that single 5-HT neurons are influenced by more than one feedback pathway.

Clues regarding the physiological and pathophysiological importance of 5-HT<sub>1A</sub> autoreceptors have arisen in part from studies of the behavioral effects of 5-HT<sub>1A</sub>

receptor agonists and antagonists, aided by evidence that these receptors (at least in some conditions) are tonically active (see above). In the case of the postsynaptic 5-HT<sub>2</sub> feedback systems, there are many behavioral effects associated with 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptor activation (Barnes and Sharp, 1999), but the possibility that these effects link in some way to 5-HT feedback mechanisms has not yet been considered. Data so far suggest that the 5-HT<sub>2A/C</sub> receptor feedback mechanisms are not tonically active. That is, in electrophysiological and microdialysis studies to date 5-HT<sub>2A/C</sub> receptor antagonists did not increase 5-HT cell firing or release. However, demonstration of tone at 5-HT<sub>1A</sub> autoreceptors has been problematic, and required specific experimental conditions (see above). It is theoretically possible that tone on any one feedback mechanism may be difficult to reveal using antagonists, because blockade of one mechanism may result in compensatory changes in another. Against this argument, evidence suggests that the 5-HT<sub>4</sub> feedback is under the tone of endogenous 5-HT, since 5-HT<sub>4</sub> receptor antagonists alone decreased 5-HT cell firing (Lucas and Debonnel, 2002; Lucas *et al.*, 2005).

**Figure 5** Effect of the 5-HT<sub>2</sub> agonist DOI on Fos immunoreactivity in DRN neurons immunopositive for the GABA marker, glutamate decarboxylase (GAD). In (A), DOI (2 mg/kg i.p.) was administered in combination with the 5-HT<sub>2A</sub> selective antagonist MDL 100907 (0.3 mg/kg i.p.). In (B), DOI (2 mg/kg i.p.) was administered in combination with the 5-HT<sub>2C</sub> selective antagonist SB 242084 (0.5 mg/kg i.p.). Note the increase in Fos/GAD double-labeled neurons by DOI and selective blockade by MDL 100907. \* $P < 0.001$  versus vehicle controls. Data taken from Raley *et al.* (2004).

From a physiological perspective, it may be relevant that the mPFC–DRN and LHb–DRN pathways are emerging as key neuroanatomical substrates for postsynaptic 5-HT feedback control, because both pathways are thought to play important roles in mediating the impact of stress. In particular, it is proposed that the mPFC–DRN pathway protects DRN 5-HT neurons from excessive activation by prolonged stress that results in behaviors characteristic of depression (learned helplessness) (Amat *et al.*, 2005). Thus, in animals, chemical inactivation of the mPFC–DRN pathway led to amplification of the effect of stress, such that controllable stress assumed the deleterious impact of uncontrollable stress (Amat *et al.*, 2005). In this respect, there is evidence that the LHb–DRN pathway may play a similar role to the mPFC–DRN pathway (Amat *et al.*, 2001).

Therefore, one possible physiological function of certain postsynaptic 5-HT feedback mechanisms is to sense and control stress-evoked changes in 5-HT availability. Thus, postsynaptic feedback systems utilizing 5-HT receptors in the mPFC (5-HT<sub>1A</sub>, 5-HT<sub>2A</sub>, 5-HT<sub>4</sub>) and LHb (5-HT<sub>2C</sub>) might act in unison with presynaptic 5-HT autoreceptors (5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>) to provide the necessary balancing influence of inhibitory and excitatory feedback control on 5-HT neurons and mitigate against adverse environmental stimuli such as excessive stress. Recently genetically engineered mice with forebrain and even cortex-specific modulations of 5-HT receptor expression have been developed (Gross *et al.*, 2002; Weisstaub *et al.*, 2006). This technology may allow further testing of the importance of postsynaptic 5-HT receptor-mediated feedback in stress control mechanisms.

#### *Novel therapeutic strategies exploiting postsynaptic feedback*

As noted above, much effort has been invested in translating knowledge of 5-HT<sub>1</sub> autoreceptor pharmacology to the development of ligands for therapeutic use, particularly in the areas of depression and anxiety. In the same way, knowledge of the pharmacology of postsynaptic 5-HT feedback might open up interesting therapeutic possibilities. Indeed, recent preclinical data show that 5-HT<sub>2C</sub> receptor antagonists enhance the effect of 5-HT reuptake inhibitors on 5-HT function (Cremers *et al.*, 2004), and 5-HT<sub>2A</sub> receptor antagonists may also have this effect (Boothman *et al.*, 2006a). This 5-HT enhancing property of 5-HT<sub>2C</sub> and 5-HT<sub>2A</sub> receptor antagonists has been associated with antidepressant augmenting effects of these agents in animal models (Marek *et al.*, 2003; Cremers *et al.*, 2004). The latter observation is consistent with

clinical evidence that drugs with 5-HT<sub>2</sub> receptor antagonist properties (e.g., risperidone, olanzapine) enhance the therapeutic effect of SSRIs in treatment-resistant depression (Marek *et al.*, 2003). Interestingly, 5-HT<sub>4</sub> receptor agonists were recently found to have antidepressant effects in preclinical models (Lucas *et al.*, 2007), which might link to the excitatory 5-HT<sub>4</sub> feedback mechanism causing increased 5-HT output.

The above data clearly advocate the further testing of antagonists that block 5-HT<sub>1</sub> and 5-HT<sub>2</sub> negative feedback mechanisms, and agonists that activate the 5-HT<sub>4</sub> positive feedback mechanism, in antidepressant combinations (or dual action drugs) in clinical trials. The possibility of synergistic effects of blocking multiple 5-HT feedback systems is another avenue of clinical (and preclinical) research, although the safety of this approach would need to be proven. Continued investigation of other 5-HT feedback mechanisms (5-HT<sub>6</sub>, 5-HT<sub>7</sub>) might also encourage the identification of novel pharmacological strategies for translating to humans.

## Conclusion

Feedback control appears to be a key mechanism maintaining 5-HT neurons under homeostatic control. Evidence for feedback inhibition by presynaptic 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> autoreceptors is well established. These autoreceptors are implicated in the treatment of depression and anxiety, and form the basis of various 5-HT drug discovery efforts in these therapeutic areas. Recent findings have discovered that feedback control of 5-HT neurons also involves 5-HT receptors located on postsynaptic targets. These postsynaptic feedback mechanisms utilize multiple 5-HT receptor subtypes (5-HT<sub>1A</sub>, 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> and 5-HT<sub>4</sub> receptors, although there may be more) and appear to operate via neural pathways that input to 5-HT neurons. In this respect, inputs from the mPFC and LHb are emerging as particularly important. The physiological role of these postsynaptic feedback mechanisms is unknown, but it is argued herein that they act in unison with 5-HT autoreceptors to sense and control extreme changes in 5-HT availability such as might be evoked by high levels of stress. New findings suggest that drugs targeting these feedback systems may have therapeutic utility in depression and other psychiatric disorders.

## Acknowledgements

This work was supported by a grant from the European Community (FP6 Integrated Network; NEWMOOD,

LMSH-CT-2004-503474), and studentships from Wellcome Trust, MRC and the Government of Jersey. The excellent scientific and technical contributions to this work of Laura Boothman, Josie Raley and Philip Qu  r  e are gratefully acknowledged.

# Tryptophan Depletion and Serotonin Release – A Critical Reappraisal

Matthijs G.P. Feenstra<sup>\*,1</sup> and Geoffrey van der Plasse<sup>2</sup>

<sup>1</sup>*Netherlands Institute for Neuroscience, An Institute of the Royal Netherlands Academy of Arts and Sciences, Amsterdam, The Netherlands*

<sup>2</sup>*Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, Utrecht University Medical Centre, Utrecht, The Netherlands*

**Abstract:** Tryptophan depletion is often assumed to lead to a decrease in neuronal serotonin release in the brain. Here we review the literature and show that only in animal studies in which either serotonin synthesis rate is already decreased or serotonin utilization is increased has an effect of tryptophan depletion on serotonin release been demonstrated. In the absence of convincing evidence for reduced central serotonin release, the possibility that other mechanisms are involved cannot be discarded. We therefore conclude that one should be careful to interpret tryptophan depletion-related effects as reflecting a widespread reduction of central serotonin release.

**Keywords:** tryptophan depletion, serotonin release, serotonin synthesis, serotonin receptors, microdialysis, tryptophan-free diet, 5-hydroxyindoleacetic acid, cerebrospinal fluid.

## Introduction

Tryptophan depletion was introduced about 30 years ago as an experimental method to obtain a rapid and reversible decrease of the concentration of serotonin in the brain (Biggio *et al.*, 1974; Gessa *et al.*, 1974). By ingestion of a mixture of amino acids without the serotonin precursor tryptophan, the rate of serotonin synthesis in the brain is strongly decreased (Nishizawa *et al.*, 1997). Since its introduction in human psychopharmacology (Young *et al.*, 1985), this method has been used increasingly as a relatively simple and safe method to assess serotonergic functions. A PubMed search delivers about 50 articles per year for 'tryptophan depletion', and the popularity of the method appears still to be increasing.

Most authors tacitly assume that tryptophan depletion will reliably and reproducibly decrease serotonin transmission because of its effect on synthesis. However, this is only possible if serotonin release and binding to postsynaptic receptors is affected, as well. While some authors indeed mention this explicitly, the actual evidence is extremely sparse and often misquoted. Therefore, we will review what evidence is available to support that tryptophan depletion affects serotonin release and serotonin receptor binding.

## Tryptophan depletion

The rate-limiting step in the synthesis of serotonin is the hydroxylation of tryptophan to 5-hydroxytryptophan by tryptophan hydroxylase, the enzymatic marker of serotonin neurons. This means that synthesis is directly dependent on the supply of the precursor, tryptophan. Free plasma concentrations of this essential amino acid are determined by its intake, plasma protein binding and utilization in a number of physiological processes, of which serotonin synthesis is only one. Tryptophan can enter the brain through active uptake by a carrier shared with other large, neutral amino acids. Intake of a tryptophan-free diet (Biggio *et al.*, 1974) or a mixture of essential amino acids (Gessa *et al.*, 1974) leads to increased demand for tryptophan for protein synthesis and decreased brain uptake. Blocking protein synthesis indeed prevents the effect on brain uptake (Moja *et al.*, 1991). Thus, plasma and brain concentrations of tryptophan are strongly decreased, and this leads to decreased concentrations of serotonin and its metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the brain tissue (Biggio *et al.*, 1974; Gessa *et al.*, 1974). Whether this decrease will have consequences for serotonergic neurotransmission depends on the utilization (i.e., the net loss) of the transmitter because of activity-dependent release and metabolism. If utilization is too high in comparison to the reduced synthesis, releasable pools of

\*Corresponding author

serotonin will be exhausted and serotonergic function will be affected.

Numerous physiological, pharmacological and behavioral experiments have been carried out after tryptophan depletion, and these have been reviewed regularly (Delgado *et al.*, 1989; Young and Teff, 1989; Reilly *et al.*, 1997; Fadda, 2000; Moore *et al.*, 2000; Bel *et al.*, 2001; van der Does, 2001; Riedel *et al.*, 2002; Booij *et al.*, 2003; Fusar-Poli *et al.*, 2006; Evers *et al.*, 2007; Ruhé *et al.*, 2007). An important issue is that tryptophan depletion is often used to prove that a function is dependent on serotonergic activity or not – i.e., as an ‘acid test’ for serotonergic involvement. We feel that the evidence for this is not strong enough. For a reliable use of the test, unequivocal evidence should be available that tryptophan depletion reproducibly decreases serotonin release and serotonergic transmission. We will argue that this is not the case, and that the effects strongly depend on the precise experimental conditions. We will review the evidence that tryptophan depletion affects serotonergic neuronal activity, serotonin release and serotonin receptor activation in the following sections.

### Effects of tryptophan depletion on 5-HT release and neuronal activity

The firing activity of serotonergic neurons in the raphe nuclei is subject to serotonergic control through autoreceptors. Increases or decreases in extracellular serotonin from dendritic or collateral release are reflected in decreased or increased neuronal activity, respectively. Early studies showed that the former effect, decreased neuronal activity, was indeed consistently observed after tryptophan administration (Aghajanian, 1972; Trulson and Jacobs, 1975). A tryptophan-free diet, however, did not significantly change firing in cats, even though brain tryptophan, serotonin and 5-HIAA concentrations were decreased (Trulson, 1985).

The same author showed that serotonin release measured by push–pull perfusion was not affected in this condition, although the concentrations of 5-HIAA in the perfusate were decreased. Later studies of extracellular serotonin concentrations used microdialysis sampling, which is now the method of choice to determine serotonin neuronal release (Westerink, 1995). These studies are summarized in Table 1. Our conclusion is that serotonin release is only reduced by tryptophan depletion when the diet is chronically administered, when a serotonin-reuptake inhibitor is used, or when serotonin release is strongly stimulated. The effect of chronic administration of the diet is clearly illustrated by the results of Fadda and colleagues (Fadda, 2000; Fadda *et al.*, 2000a, 2000b), who

showed that administration of the diet for 3–5 days leads to steadily decreasing extracellular levels of serotonin in rat hippocampus and frontal cortex. Chronic administration of such diets is also known to affect body weight (see, for example, D’Souza *et al.*, 2004; Cahir *et al.*, 2007) and plasma corticosterone levels (D’Souza *et al.*, 2004). It cannot be expected that the physiological or neurochemical alterations after long-term diet administration are exclusively dependent on serotonergic mechanisms.

Addition of serotonin reuptake blockers to the dialysis fluid was often applied in older studies to increase the extracellular concentrations, and therefore the detectability of serotonin in the dialysates. However, it has long been known that reuptake blockade leads to decreased serotonin synthesis rates (Carlsson and Lindqvist, 1978), and this will increase the chances that synthesis cannot keep up with utilization when the tryptophan availability is reduced. The effect of uptake inhibition is clearly demonstrated in the set of experiments reported by Bel and Artigas (1996), who studied the effects of peripheral administration of the uptake blocker fluvoxamine. Only after chronic fluvoxamine did tryptophan depletion lead to decreased serotonin release in the dorsal raphe nucleus or frontal cortex; after saline treatment, no effect was observed. Fasting or feeding the rats before the experiment did not alter the fluvoxamine effect.

Gartside *et al.* (1992b) also reported no effect on basal release of tryptophan depletion by treatment with one of the essential amino acids that competes with tryptophan, i.e. valine. However, they observed a reduced effect of electrical stimulation of the raphe nucleus or administration of fenfluramine, resulting in two-fold and six-fold increases of release in control animals, respectively (Gartside *et al.*, 1992a, 1992b). It would be interesting to test whether normal, physiological activation of serotonergic activity would also uncover the effects of tryptophan depletion on *in vivo* serotonin release. Van der Plasse *et al.* (2007) exposed rats to a novel environment and measured release after administration of the tryptophan-free diet. However, this stimulus was apparently too weak to activate serotonin release. More conclusive evidence might be obtained by combining tryptophan depletion with studies of *in vivo* release under conditions of more consistently increased serotonergic activity, such as motor activity (Jacobs and Fornal, 1997) or stress (Amat *et al.*, 2005).

A further issue that has not been taken into account is the differential innervation of brain areas by the median and dorsal raphe nuclei. These form two distinct serotonergic systems, with different morphological and pharmacological properties (Molliver, 1987). As differences have been shown to exist in stress-induced serotonin release and the effects of chronic uptake inhibition in these systems (Auerbach and

**Table 1** Effects on serotonin release

*Abbreviations:* AA, amino acid; anesth, anesthetized; chron, chronic; d, dorsal; fluvox, fluvoxamine; ip, intraperitoneal; sc, subcutaneous; signif, significant; trp, tryptophan.

Hjorth, 1995; Storey *et al.*, 2006), it would be interesting to study their response to tryptophan depletion.

In conclusion, only in conditions of enhanced serotonin utilization or reduced serotonin synthesis has an effect of tryptophan depletion on serotonin release been demonstrated.

Direct measurements of serotonin extracellular concentrations in primate brain tissue have not been reported, but a few studies were performed using cerebrospinal

fluid (CSF), which is in direct contact with the extracellular fluid of the brain and spinal cord. All studies showed profound decreases of tryptophan concentrations in plasma, CSF or brain tissue, and furthermore reported 5-HIAA decreases of 30 percent (Table 2). No study, however, reported on serotonin concentrations. The value of 5-HIAA measurements is limited, as extracellular concentrations of 5-HIAA cannot be expected to be a reliable indicator of neuronal serotonin release (Crespi, 1990).

Deaminated monoamine acidic metabolites are not stored in the neuron, like the parent transmitter, but freely exchange between intra- and extracellular spaces. Their concentration is determined by the metabolism of released, but also of newly synthesized, transmitter, and by active transport out of the brain by the probenecid-sensitive carrier (Westerink, 1995). While extracellular 5-HIAA may show changes similar to those of serotonin, this is not necessarily the case, and differential effects may be expected when either uptake or synthesis is altered (Stenfors and Ross, 2004; van der Stelt *et al.*, 2005). In summary, alterations in CSF 5-HIAA levels cannot be taken as proof of altered serotonin release.

Another outcome of all these studies is that a profound reduction of plasma tryptophan, the usual measure of the effectiveness of tryptophan depletion in human studies, is not necessarily associated with decreased *in vivo* serotonin release in the brain. A clear example is provided by van der Plasse *et al.* (2007), who showed strongly decreased plasma tryptophan in the absence of a significant alteration of rat-brain serotonin release. While this should be confirmed in other studies, it supports the conclusion that a central imbalance between serotonin synthesis and utilization is needed to observe an effect of tryptophan depletion.

Effects of tryptophan depletion on serotonin receptors

An alternative approach to study the effects of tryptophan depletion on serotonin release is to determine *in vivo* occupation of serotonin receptors or serotonin receptor-mediated effects or *ex vivo* receptor numbers. An overview of the few studies that have been performed is presented in

Table 2 Measurements in primates

Release, synthesis	Measurement	Subjects	Method	Biochemical effect	Effect on 5-HT	Reference
CSF concentrate	Cisternal CSF	Vervet monkey	Fast; AA mixture	CSF −61% trp; −34% 5-HIAA	Not measured	Young <i>et al.</i> , 1989
5-HT synthesis	Human PET; <sup>11</sup> C-Me-L-Trp	Volunteers	Diet; AA drink	Plasma −72% trp; synth rate −87% male; plasma −89% trp; synth rate −97% female	Not measured	Nishizawa <i>et al.</i> , 1997
CSF concentrate	Lumbar CSF	Volunteers	Diet; AA drink	Plasma −89% trp; CSF −92% trp; −31% 5-HIAA	Not measured	Carpenter <i>et al.</i> , 1998
CSF concentrate	Lumbar CSF	Volunteers	Diet; AA drink	Plasma −86% trp; CSF −92% trp; −33% 5-HIAA	Not measured	Williams <i>et al.</i> , 1999

Abbreviations: AA, amino acid; CSF, cerebrospinal fluid; Me-L-trp, α-methyl-L-tryptophan; PET, positron emission tomography; synth, synthesis.

Table 3. Decreased serotonin release should be reflected as an increase in radioligand binding potential. This has not been reported. Human PET studies of radioligand binding to 5-HT<sub>1A</sub> receptors after tryptophan depletion did not detect any alteration, which is remarkable, as a study of the effects of inhibition of tryptophan hydroxylase on 5-HT<sub>1A</sub> binding in rats using the same radioligand (<sup>18</sup>F-MPPF) did report the expected clear increase in binding (Zimmer *et al.*, 2003). The only study of 5-HT<sub>2</sub> receptors did not detect an increase, but rather a decrease, in binding potential (Yatham *et al.*, 2001).

Animal studies on receptor-occupancy or receptor-mediated effects are sparse, too (Table 3). Moreover, most of the results were obtained after chronic tryptophan-free or low-tryptophan diets (and not all these experiments are reported here). The only acute effect is a decrease in 5-HT<sub>1A</sub> receptor numbers in the raphe nucleus (Cahir *et al.*, 2007), which again cannot be explained by a reduction in occupancy by serotonin. Instead, the authors suggest a homeostatic response to reduce autoreceptor feedback, and they discuss the possibility that alterations in corticosterone release might mediate this effect. Others, however, conclude that serotonin is only involved in cortisol/corticosterone release in response to stress, but not under basal conditions (Porter *et al.*, 2007).

Thus, none of these studies provides any evidence of decreased serotonin release after tryptophan depletion.

Other effects of tryptophan depletion – alternative mechanisms

As was mentioned previously, tryptophan is used in many physiological processes, both peripherally and centrally.

**Table 3** Receptor measurements

Receptor	Receptor measurement	Subjects	Method	Biochemical effect	Effect on receptor	Reference
5-HT <sub>1A</sub>	Human PET; <sup>18</sup> F-MPPF	Volunteers	Diet; AA drink	–62% plasma trp	No signif eff	Udo de Haes <i>et al.</i> , 2002

5-HT <sub>2C</sub>	Prolactin resp; rec binding brain	Rat	6-week low-trp diet	–40–60% plasma trp –43% cortex 5-HTP	+36% AUC resp agon no signif eff rec number	Franklin <i>et al.</i> , 1999

**Abbreviations:** AA, amino acid; ACTH, adrenocorticotroph hormone; agon, agonist; AUC, area-under-the-curve; BP, binding potential; chron, chronic; corticost, corticosterone; FCo, frontal cortex; FCWAY, Trans-4-Fluoro-N-(2-[4-(2-methoxyphenyl)piperazin-1-yl]ethyl)-N-(2-pyridyl) cyclohexanecarboxamide; MPPF, (4-(2'-methoxyphenyl)-1-[2'-(N-2"-pyridinyl)-p-fluorobenzamido]-ethyl piperazine); OXT, oxytocine; PET, positron emission tomography; rec, receptor; resp, response; signif eff, significant effect; trp, tryptophan.

While the possible consequences of a reduction of central serotonin synthesis receive most attention, it cannot be excluded that other processes are involved in the physiological or behavioral effects that have been reported after tryptophan depletion. Therefore, we need to consider first whether serotonergic or non-serotonergic peripheral processes might be involved in these effects, and second, whether non-serotonergic central processes might play a role.

### Peripheral processes

Despite the fact that only 5 percent of the total amount of serotonin present in the body is found in the brain, and that serotonin receptors are distributed throughout the body (see, for example, Ramage and Villalón, 2008),

relatively little is known about consequences of tryptophan depletion on serotonergic functions outside the brain. Serotonin has been implicated as an important modulator of cardiovascular and gastrointestinal activity. Although peripheral mechanisms can be expected to predominate, these processes may also partly depend on central serotonin availability. It is thus not surprising that tryptophan has been suggested to link somatic and psychiatric illnesses (Russo *et al.*, 2003). The fact that most serotonin is synthesized and utilized peripherally supports such a notion.

Peripheral serotonin is synthesized in, and released from, the enterochromaffin cells of the intestinal system. It is known to be involved in the regulation of gastrointestinal activity (Kilkens *et al.*, 2004), and tryptophan depletion affects gastric emptying in healthy female controls (van Nieuwenhoven *et al.*, 2004). A potentially important

observation is that tryptophan depletion in a control group and in patients with irritable bowel syndrome (IBS) not only impaired affective memory performance, but also heightened visceral perception. Shuffelbotham *et al.* (2006) replicated these findings in patients with IBS, but not in healthy controls.

Central as well as peripheral actions of serotonin on cardiovascular output have been well described. In short, serotonin acts both directly via the raphe nucleus on (para)sympathetic innervation, and as a modulator on serotonergic receptors on the smooth muscle tissue of the heart and vascular system. As such, serotonin receptor activation has been shown to increase, as well as decrease, heart rate (Jonnakuty and Gragnoli, 2008), and to regulate blood pressure (Nilsson *et al.*, 1999). The effect of tryptophan depletion on these variables remains, however, unclear. A 2-day dietary depletion of tryptophan enhanced stress-induced increases in blood pressure in recovered anxiety patients treated with serotonin-reuptake inhibitors (Davies *et al.*, 2006), but Roiser *et al.* (2008) did not observe any change in blood pressure or heart rate after acute tryptophan depletion in healthy controls. A study by van der Veen *et al.* (2008) has, to the best of our knowledge, been the only one to find a correlation between tryptophan depletion and cardiac slowing, although the authors attributed this to an effect of task rather than a depletion of serotonin levels.

These examples are illustrative of the idea that perception of bodily functions (e.g., increased heart rate or gastrointestinal activation) affects cognitive appraisal – an idea that is certainly not new. The influential concept was originally posed in the nineteenth century by William James and Carl Lange, and later took the form of the somatic-marker hypothesis posed by Damasio (1996). This model, in essence, entails the notion that affective signals from the body are used to guide decision-making, and as such play an important role in the expression of behavior.

Although the exact nature of peripheral effects induced by (acute) tryptophan depletion is poorly understood, there are positive indications that tryptophan depletion does affect functions outside the brain that deserve consideration when interpreting the central effects of tryptophan depletion.

### **Central processes**

In addition to possible effects of tryptophan depletion on peripheral processes, an important question is the extent to which tryptophan depletion might directly exert its effects through modulation of other central monoamines. Effects of tryptophan depletion might be expected, as

the catecholamine precursor tyrosine is one of the amino acids that are administered and that compete for transport over the blood–brain barrier (Badawy, 2005). However, *in vivo* microdialysis studies showed that neither noradrenaline nor dopamine release was altered after tryptophan depletion in rats (Fadda *et al.*, 2000b; van der Plasse *et al.*, 2007). In addition, brain concentrations of these neurotransmitters and their metabolites were not affected (Lieben *et al.*, 2004a; Ardis *et al.*, 2008). Even tyrosine concentrations were not consistently altered (Lieben *et al.*, 2004a; Jans *et al.*, 2007a).

Measurements in CSF indicated that tyrosine concentrations were not changed (Young *et al.*, 1989) or increased (Carpenter *et al.*, 1998) while, again, dopamine and noradrenaline metabolites were not altered. Therefore, there is no indication that tryptophan depletion leads to alterations in brain catecholamines that might explain the physiological and behavioral effects.

Effects of tryptophan depletion on non-serotonergic processes that use tryptophan have not been studied in great detail. However, Lieben *et al.* (2004b) performed a pilot study on the effect of tryptophan depletion on kynurenine-related metabolites in serum, liver and brain. An interesting finding was that tryptophan was decreased in serum and brain, but not in liver. In liver, only the concentration of quinolinic acid was decreased, but the brain concentrations of neither kynurenine, nor kynurenic acid or quinolinic acid were decreased (Lieben *et al.*, 2004b), making it unlikely that tryptophan depletion affects central processes through this pathway.

### **Consequences for the interpretation of tryptophan-depletion induced effects**

The greatest impact that the tryptophan-depletion method has made is undoubtedly in the field of psychiatry. Since the reports that tryptophan depletion may lower mood in normal males (Young *et al.*, 1985) and in remitted depressed patients (Delgado *et al.*, 1990), this method has been used to study serotonergic involvement in psychiatric disorders (Reilly *et al.*, 1997; Bel *et al.*, 2001; van der Does, 2001; Booij *et al.*, 2003). Recently, attention has increasingly been directed to the use of tryptophan depletion in cognitive research, as well (Park *et al.*, 1994; Riedel *et al.*, 1999; Riedel, 2004; Fusar-Poli *et al.*, 2007). Tryptophan-depletion studies now form the basis for novel theories about the role of serotonin in behavior and cognition (Evers *et al.*, 2007; Cools *et al.*, 2008).

However, before we accept the apparent use of tryptophan depletion as an ‘acid test’ for serotonergic involvement in human clinical and cognitive research, we have to

return to our earlier conclusion that tryptophan depletion only decreases serotonin release and function in specific conditions – i.e., treatment with serotonin reuptake blockers, reduced serotonin synthesis and increased serotonin utilization. Recent clinical literature indeed shows that the reported effects of tryptophan depletion are not always reproducible. Indications that effects are observed only in special experimental conditions or only in subpopulations of either patients or normal controls abound in the literature. Thus, the effectiveness of tryptophan depletion as a method for studying serotonin involvement in mood is restricted to subpopulations that show a vulnerability to serotonin dysregulation (Fadda, 2000; Booij *et al.*, 2003; Fusar-Poli *et al.*, 2006; Jans *et al.*, 2007b; Ruhé *et al.*, 2007). These subgroups include remitted depressed patients (generally those treated with selective serotonin reuptake inhibitors; see Bremner *et al.*, 1997; Young and Leyton, 2002; Neumeister *et al.*, 2004), females (who show lower synthesis rates; see Ellenbogen *et al.*, 1996; Nishizawa *et al.*, 1997; Schmitt *et al.*, 2000; Booij *et al.*, 2002) and subjects with certain genetic variations in the serotonin transporter gene (associated with reduced serotonin reuptake; see Roiser *et al.*, 2006; Finger *et al.*, 2007). Based on the animal data, one might add that the level of activation due to different task demands and its interaction with the biological vulnerability will prove to be an important factor, as well.

The examples mentioned in the section on peripheral processes also suggest that the effects of tryptophan depletion probably depend on the individual vulnerability of the participants. The same should apply to the studies of animal and human cognition. Regarding the human studies, the issue is further complicated by the fact that many studies using tryptophan depletion report changes in brain activation measured by functional MRI, in the absence of effects on performance or mood (Fusar-Poli *et al.*, 2007; Anderson *et al.*, 2008). Given the uncertainty regarding underlying mechanisms, the inferences for serotonergic functions of these results remain tentative.

The possibility that individual differences in emotional processing and its underlying biological processes are a major factor in the variability of tryptophan-depletion induced effects on cognition has been raised (Evers *et al.*, 2007; Harmer, 2008). Supportive evidence was recently provided by (1) the work of Sambeth *et al.* (2007), who found that impairments in memory recall after tryptophan depletion were stronger in females than in males, and (2) the work of Olivier *et al.* (2008), who tested object memory in rats with genetic deletions of the serotonin transporter. Tryptophan depletion led to similar effects on plasma tryptophan in all genotypes, but differential effects on brain serotonin concentrations and object recognition.

## Conclusion

The evidence that tryptophan depletion leads to a reduction of serotonin release and transmission is sparse, and is restricted to animal studies in which either serotonin synthesis rate is already decreased or serotonin utilization is increased. The variability in the results of human tryptophan depletion studies can tentatively be explained by taking the biological vulnerability and the task demands into account. However, in the absence of convincing evidence for reduced central serotonin release, the possibility that other mechanisms are involved cannot be discarded. We conclude that one should be careful to interpret tryptophan depletion-related effects as reflecting a widespread reduction of central serotonin release.

**Abstract:** Serotonergic fibers in the brain originate from a small number of cell bodies confined to the raphe nuclei of the brainstem and spread profusely, giving rise to an extensive arborization of axons in terminal fields. For this reason, it is not surprising that the brain serotonergic system is involved in several physiological as well as pathological conditions, and the regulation of serotonergic transmission at the level of raphe nuclei is of crucial importance in terms of serotonin (5-HT) action in nerve endings. The mechanisms that are responsible for the regulation of serotonergic transmission can be divided into intrinsic, i.e. those circumscribed to the internal function of 5-HT cells, and extrinsic, i.e. those that depend fundamentally on the interaction between other transmitter systems. The afferent connections of the raphe nuclei provide the neuroanatomical substrate for the interaction between different brain areas and serotonergic neurons. However, it is worth noting that these interactions are reciprocal. In this chapter we summarize the mutual interactions between serotonin and noradrenaline, dopamine, acetylcholine, GABA and glutamate. The considerable amount of interest in those interactions is due to the critical role they appear to play in mental functions. Special attention has been paid to the reciprocal control of the prefrontal cortex (PFC) and the midbrain raphe nuclei, which are involved in psychiatric diseases like major depression and schizophrenia.

**Keywords:** serotonin, noradrenaline, dopamine, acetylcholine, GABA, glutamate, raphe, prefrontal cortex.

## Introduction

Most of the neurons synthesizing serotonin (5-HT) in the central nervous system are located in the raphe nuclei of the brainstem, and serotonergic terminals can be found in virtually every brain region (Jacobs and Azmitia, 1992;

Halliday *et al.*, 1995; Leger *et al.*, 2001). With this widespread distribution, it is not surprising that serotonin has a role in many physiological functions as well as pathological states. Interactions between serotonergic and other transmitter systems can be found at the level of 5-HT cell bodies of the raphe nuclei and the level of serotonergic terminals in a great variety of brain areas. In both locations these interactions can be bidirectional – i.e., release of 5-HT may influence other transmitter systems, which in turn can also have an impact on serotonergic

E-mail: aacnqi@iibb.csic.es

transmission. The knowledge of these interactions in complex neuronal circuits may pave the way to a powerful pharmacological approach for the development of therapeutic strategies directed to severe psychiatric conditions such as depression and schizophrenia. The neuromodulatory effects of 5-HT on diverse transmitter systems can be achieved through multiple postsynaptic 5-HT receptors, although the precise molecular mechanisms by which this synaptic efficacy is affected remain to be fully elucidated. Several papers have reviewed the main features of transmitter receptors that can regulate 5-HT firing and release at the level of raphe nuclei (Jacobs and Azmitia, 1992; Piñeyro and Blier, 1999; Adell *et al.*, 2002). In this chapter, we will update previous data on this matter and also focus on the interaction of 5-HT with other transmitter systems at the level of the prefrontal cortex (PFC). The PFC is involved in many higher brain functions, including mnemonic processes, executive functions, goal-directed behavior, working memory and control of emotional signals (Fuster, 2001; Miller and Cohen, 2001; Romo and Salinas, 2003). To this end, PFC functions rely on its extensive and usually reciprocal connections with a vast array of cortical and subcortical structures (Groenewegen and Uylings, 2000; Fuster, 2001; Miller and Cohen, 2001). The PFC, as the rest of cortical areas, is formed predominantly by excitatory (glutamatergic) and inhibitory (GABAergic) neurons. Glutamatergic (pyramidal) neurons project to cortical and subcortical areas and GABAergic interneurons tightly control the activity of pyramidal neurons, thus providing the level of inhibition necessary for the regular functioning of cortical operation. Pyramidal neurons located in layer V of the medial PFC (mPFC) project heavily to the dorsal raphe nuclei (DR) (Hajós *et al.*, 1998; Peyron *et al.*, 1998; Vertes, 2004; Gabbott *et al.*, 2005), which in turn send serotonergic innervation back to the mPFC. This serotonergic projection can impinge upon both pyramidal and GABAergic neurons and exert excitatory (through 5-HT<sub>2A</sub>, 5-HT<sub>3</sub>, 5-HT<sub>4</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub> receptors) and inhibitory (mainly through 5-HT<sub>1A</sub> receptors) actions on either neuronal type. The global influence of the serotonergic system on the PFC will thus depend directly on the final balance of the action of the transmitter upon all of its receptors. However, serotonergic neurons of the DR also send projections to other brainstem monoaminergic nuclei, such as the nucleus locus coeruleus (LC) and ventral tegmental area (VTA), which may exert an important regulation of cortical activity through their respective projections. In this chapter, the functional interactions between 5-HT and other transmitter systems, such as noradrenaline, dopamine, acetylcholine, GABA and glutamate, are discussed with the focus on microdialysis and electrophysiological studies in the rodent brain.

## Noradrenaline

### *Influence of 5-HT receptors on brain noradrenaline*

There is a serotonergic projection from the DR to the LC (Vertes and Kocsis, 1994; Luppi *et al.*, 1995; Kaehler *et al.*, 1999), which appears to exert an inhibitory role, since the lesion of serotonergic neurons enhanced the firing activity of the noradrenergic cells of the LC (Haddjeri *et al.*, 1997). The 5-HT<sub>1A</sub> receptor agonist, 8-OH-DPAT, and the 5-HT<sub>1A</sub> receptor antagonist, WAY 100635, enhanced and suppressed, respectively, the firing activity of LC noradrenergic neurons (Szabo and Blier, 2001). These actions were entirely dependent on intact serotonergic neurons. The inhibitory effects of WAY 100635 were antagonized by M100907, which suggests an involvement of 5-HT<sub>2A</sub> receptors. The absence of 5-HT<sub>2A</sub>-immunolabeling in the LC (Fay and Kubin, 2000), however, seems to indicate that this population of 5-HT<sub>2A</sub> receptors is located elsewhere in the brain. It is possible that 5-HT<sub>2A</sub> located in the mPFC may play a role in these effects through its excitatory influence on the LC (Arnsten and Goldman-Rakic, 1984; Jodo *et al.*, 1998; Vertes, 2004). In fact, the intra-mPFC perfusion of the 5-HT<sub>2A/2C</sub> agonist DOI elicits an increase in the extracellular concentration of noradrenaline in this region in an impulse-dependent manner (Figure 1). On the other hand, there is electrophysiological and neurochemical evidence that 5-HT<sub>2C</sub> receptors exert a tonic suppressant influence on the activity of LC noradrenergic transmission, since 5-HT<sub>2C</sub> agonists decrease the firing of LC noradrenergic cells and 5-HT<sub>2C</sub> antagonists increased the release of noradrenaline in LC and mPFC (Gobert *et al.*, 2000; Millan *et al.*, 2000). From a physiological point of

**Figure 1** The local perfusion of the 5-HT<sub>2A/2C</sub> receptor agonist DOI (100 μM) increased the release of noradrenaline in the mPFC. This effect was dependent on nerve impulse because it was abolished by the co-perfusion of tetrodotoxin (TTX; 1 μM).  $P < 0.05$  versus DOI alone.

view, it has to be taken into consideration that the mutual influence of noradrenergic and serotonergic neurons may vary across the sleep–wake cycle since both neuronal groups are REM-off. Thus, the  $\alpha_1$ -adrenoceptor agonist phenylephrine, applied in the DR, reversed the cessation of serotonergic discharge occurring during REM sleep in cats (Sakai and Crochet, 2000).

### ***Influence of noradrenergic receptors on brain serotonin***

It is well known that noradrenergic afferents from the LC innervate the DR (Baraban and Aghajanian, 1980; Peyron *et al.*, 1996), which has been corroborated by the presence of noradrenaline and its uptake sites in the DR (Tejani-Butt, 1992; Ordway *et al.*, 1997; Strazielle *et al.*, 1999). Noradrenaline exerts a tonic facilitation of serotonergic transmission through  $\alpha_1$ -adrenoceptors (Baraban and Aghajanian, 1980; Marwaha and Aghajanian, 1982; Vandermaelen and Aghajanian, 1983; Pan *et al.*, 1994; Adell and Artigas, 1999; Bortolozzi and Artigas, 2003; Pudovkina *et al.*, 2003) located in the DRN (Pieribone *et al.*, 1994; Day *et al.*, 1997), possibly in the cell bodies of serotonergic neurons (Gallager and Aghajanian, 1976a). Consistent with their action on the firing rate of serotonergic neurons,  $\alpha_1$ -adrenoceptor antagonists decrease the release of 5-HT in projection areas (Rouquier *et al.*, 1994; Hjorth *et al.*, 1995; de Boer *et al.*, 1996; Pudovkina *et al.*, 2003). In addition to their localization in the DR, a notable amount of  $\alpha_1$ -adrenoceptors is distributed along the PFC (Palacios *et al.*, 1987; McCune *et al.*, 1993; Pieribone *et al.*, 1994; Day *et al.*, 1997; Domyancic and Morilak, 1997; Cahir *et al.*, 2004) and expressed both in pyramidal cells and GABAergic interneurons (Figure 2). The activation of these cortical  $\alpha_1$ -adrenoceptors also elicits a facilitatory action on 5-HT neurons (Figure 3). Thus, their stimulation by the  $\alpha_1$ -adrenoceptor agonist cirazoline increases the release of 5-HT not only locally in the PFC but also distally in the DRN (Amargós-Bosch *et al.*, 2003). This latter effect is likely accounted for by a stimulation of pyramidal cells projecting to the DRN (Araneda and Andrade, 1991; Marek and Aghajanian, 1999) because it is blocked by the cortical perfusion of the  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole-4-propionic acid (AMPA)/kainate receptor antagonist, NBQX, and the non-selective metabotropic glutamate receptor (mGluR) II/III agonist 1S,3S-ACPD (Amargós-Bosch *et al.*, 2003). Furthermore, there may be differences with regard to the role of  $\alpha_1$ -adrenoceptor subtypes that stimulate serotonergic transmission in the DR and PFC because the predominant subtypes in the PFC are  $\alpha_{1A}$  and  $\alpha_{1D}$  (Figure 2), whereas the  $\alpha_{1B}$ -subtype prevails in the DR (Pieribone *et al.*, 1994; Day *et al.*, 1997).

In addition to the  $\alpha_1$ -adrenoceptor, the DR also bears one of the highest densities of  $\alpha_2$ -adrenoceptors in the brain (Rosin *et al.*, 1993; Strazielle *et al.*, 1999). However, whereas the  $\alpha_1$ -adrenoceptor has an excitatory role, the  $\alpha_2$ -adrenoceptor is inhibitory. Thus, local application of the  $\alpha_2$ -adrenoceptor agonist clonidine *in vivo* reduces 5-HT release in the DR and, consequently, in the PFC (Bortolozzi and Artigas, 2003; Pudovkina *et al.*, 2003). This effect is likely due to a decrease in noradrenergic transmission, because it can be mimicked by perfusing clonidine into the LC (Pudovkina *et al.*, 2002). The inhibitory action of the  $\alpha_2$ -adrenoceptors on serotonergic transmission seems to possess a tonic nature, since the administration of  $\alpha_2$ -adrenoceptor antagonists enhances 5-HT release in the DR (Hopwood and Stamford, 2001; Bortolozzi and Artigas, 2003; Pudovkina *et al.*, 2003). It is possible that the endpoint effect of noradrenaline on  $\alpha_2$ -adrenoceptors results from a balance between its actions on  $\alpha_2$ -autoreceptors located in noradrenergic terminals and  $\alpha_2$ -heteroreceptors located on serotonergic neurons. The elevated density of  $\alpha_{2A}$ -adrenoceptor mRNA in DR (Scheinin *et al.*, 1994) suggests that this subtype is the dominant player in this nucleus. The results obtained with microdialysis are in good concordance with electrophysiological work showing that the firing rate of 5-HT cells in the DR is suppressed by  $\alpha_2$ -adrenoceptor agonists (Svensson *et al.*, 1975; Marwaha and Aghajanian, 1982) and increased by  $\alpha_2$ -adrenoceptor antagonists (Freedman and Aghajanian, 1984; Garratt *et al.*, 1991; Haddjeri *et al.*, 1996). Since  $\alpha_1$ -adrenoceptors and  $\alpha_2$ -adrenoceptors possess an opposite impact on serotonergic transmission, it is therefore possible that the actions of noradrenaline on  $\alpha_1$ -adrenoceptors are cancelled out by those on  $\alpha_2$ -adrenoceptors.

## **Dopamine**

### ***Influence of 5-HT receptors on brain dopamine***

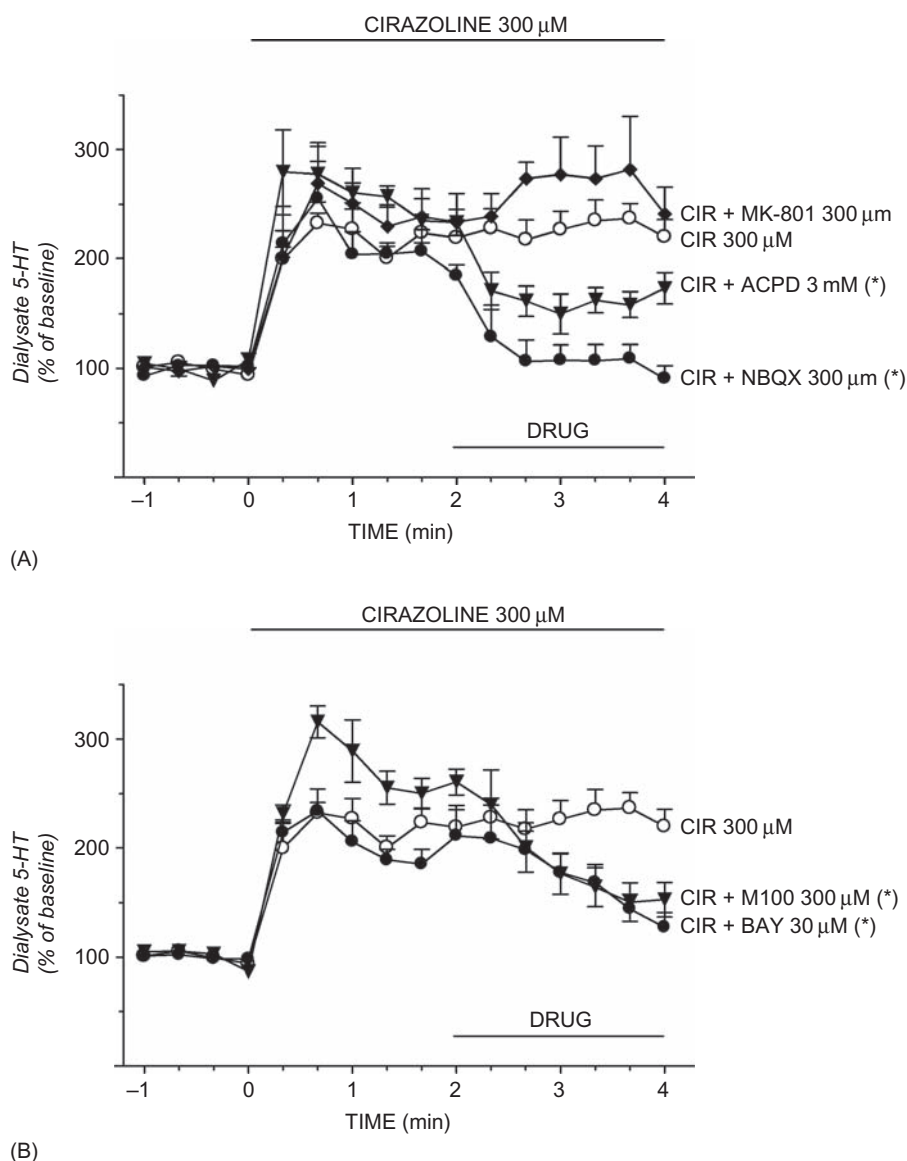

Much attention has been paid to the interaction between dopaminergic and serotonergic systems of the brain, as both systems are involved in the control of complex behaviors and implicated in the actions of drugs used to treat psychiatric illnesses. Dopamine patterns of distribution in the brain are not as diffuse as those of serotonin or noradrenaline. There are three major dopaminergic systems in the brain: the nigrostriatal system, originating in the substantia nigra pars compacta; the mesolimbic system, originating in the ventral tegmental area (VTA) and terminating in the nucleus accumbens (NAC); and the mesocortical system, originating in the VTA, but innervating the PFC. Unlike serotonin, the dopamine system

**Figure 2** (A) Low-magnification dark-field photomicrographs showing the localization of  $\alpha_{1A}$ -adrenoceptor (A1),  $\alpha_{1B}$ -adrenoceptor (A2) and  $\alpha_{1D}$ -adrenoceptor (A3) mRNAs in the rat prefrontal cortex using *in situ* hybridization histochemistry. The sections correspond approximately to AP + 3.7 mm (Paxinos and Watson, 2005). Each receptor transcript was detected with  $^{33}\text{P}$ -labeled oligonucleotides. (B) High-magnification photomicrographs showing the presence of:  $\alpha_{1A}$ -adrenoceptor (B1),  $\alpha_{1B}$ -adrenoceptor (B2) and  $\alpha_{1D}$ -adrenoceptor (B3) mRNA ( $^{33}\text{P}$ -labeled oligonucleotides, seen as silver grains) in pyramidal cells of the prelimbic area. Pyramidal neurons were identified by the presence of vGluT1 mRNA (Dig-labeled oligonucleotides). (C) High-magnification photomicrographs showing the presence of:  $\alpha_{1A}$ -adrenoceptor (C1),  $\alpha_{1B}$ -adrenoceptor (C2) and  $\alpha_{1D}$ -adrenoceptor (C3) mRNA ( $^{33}\text{P}$ -labeled oligonucleotides, seen as silver grains) in GABAergic cells of the prelimbic area. GABAergic neurons were identified by the presence of GAD<sub>65/67</sub> mRNA (Dig-labeled oligonucleotides). Red arrowheads mark cells positive for both transcripts, blue arrowheads mark cells only positive for the receptor mRNA. For the sake of simplicity, only a few cells of each type are marked. Abbreviations: ACAd, dorsal anterior cingulate cortex; PL, prelimbic area; ILA; infralimbic area; TT, tenia tecta; PIR, piriform cortex; AI, agranular insular cortex; MOs, secondary motor area (nomenclature from Swanson, 1998). Bar size: 1 mm (A1), 20  $\mu\text{m}$  (B1). To see the full color version of this figure please refer to the color plate at the back of the book. Copies produced via our print on demand service do not contain color plates. If your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

does not undergo major cyclic shifts in activity levels during the course of the sleep–wake cycle. The cell bodies and terminal regions of all three dopaminergic pathways are innervated by serotonergic neurons originating in the DR (Beart and McDonald, 1982; Hervé *et al.*, 1987; Nedergaard *et al.*, 1988; Van Bockstaele *et al.*, 1994; Broderick and Phelix, 1997). Local application of 5-HT or pharmacological or electrical stimulation of the DR

evoked excitations and/or inhibitions of VTA dopaminergic neurons (Cameron *et al.*, 1997; Gervais and Rouillard, 2000). The excitatory or inhibitory nature of this regulation may thus depend on the particular 5-HT receptor involved and the cellular type where it is expressed. Therefore, alterations in serotonergic activity could be responsible for dysregulation of dopaminergic function as inferred to occur in schizophrenia.

**Figure 3** The local perfusion of the  $\alpha_1$ -adrenoceptor agonist cirazoline (CIR, 300  $\mu$ M) increased the 5-HT release in the mPFC. (A) The effect of cirazoline was reverted by the co-perfusion of the AMPA receptor antagonist NBQX (300  $\mu$ M) and by the non-selective mGluR II/III agonist 1S,3S-ACPD (3 mM), but not by the NMDA receptor antagonist MK-801 (300  $\mu$ M). (B) The effect of cirazoline was reverted by the co-perfusion of the 5-HT<sub>1A</sub> receptor agonist BAY x 3702 (30  $\mu$ M) and by the 5-HT<sub>2A</sub> receptor antagonist M100907 (300  $\mu$ M). (\*)  $P < 0.05$  versus cirazoline alone. Data taken and redrawn from Amargós-Bosch *et al.* (2003), with permission.

Several studies have described the presence of 5-HT<sub>1A</sub> receptors in the VTA (Pazos and Palacios, 1985; Burnet *et al.*, 1995; Wright *et al.*, 1995), localized to dopaminergic as well as non-dopaminergic (Doherty and Pickel, 2001), possibly GABAergic cells (Gronier, 2008). The systemic administration of 5-HT<sub>1A</sub> receptor agonists evoked biphasic actions on VTA dopaminergic neurons. Thus, low doses increased the firing rate and the number of bursts, whereas high doses resulted in an eventual decrease of firing (Arborelius *et al.*, 1993a; Prisco *et al.*, 1994; Lejeune

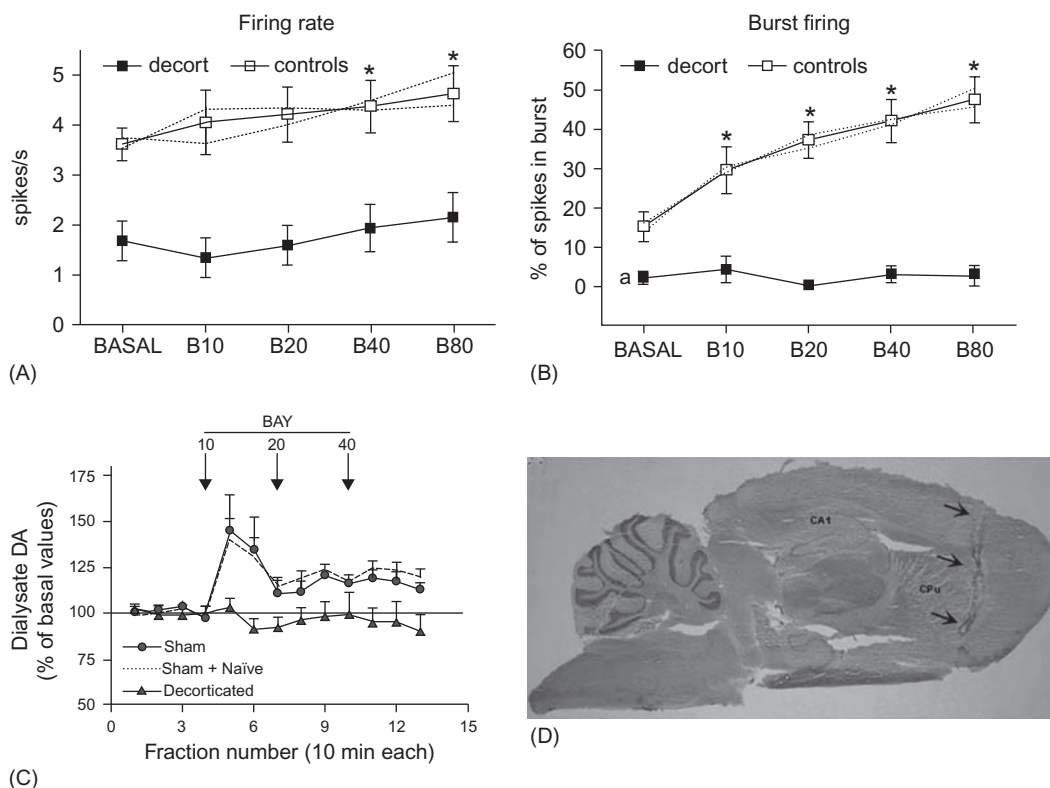

*et al.*, 1997; Lejeune and Millan, 1998; Díaz-Mataix *et al.*, 2005). Consequently, low doses of 5-HT<sub>1A</sub> receptor agonists increase dopamine release in the VTA (Chen and Reith, 1995) and the prefrontal cortex (Arborelius *et al.*, 1993b; Rasmussen *et al.*, 1994; Tanda *et al.*, 1994; Gobert *et al.*, 1998; Sakaue *et al.*, 2000), but sparing the nigrostriatal system. In line with these findings, the administration of selective 5-HT<sub>1A</sub> agonists (8-OHDPAT and BAY x 3702) increased significantly the output of dopamine in the mPFC of wild-type, but not of 5-HT<sub>1A</sub>

receptor knockout mice (Bortolozzi *et al.*, 2007), which further strengthens the role of 5-HT<sub>1A</sub> receptors in controlling dopaminergic transmission. This effect is dependent on cortical 5-HT<sub>1A</sub> receptors, since it vanished in rats subjected to PFC transection (Figure 4 Díaz-Mataix *et al.*, 2005). It is thus conceivable that low concentrations of 5-HT<sub>1A</sub> receptor agonists preferentially activate 5-HT<sub>1A</sub> receptors in GABAergic interneurons of the PFC. The presence of 5-HT<sub>1A</sub> receptors in mPFC GABAergic interneurons (Santana *et al.*, 2004), together with the reversal of the stimulatory effect of BAY x 3702 by bicuculline, suggests that low concentrations of 5-HT<sub>1A</sub> receptor agonists preferentially activate 5-HT<sub>1A</sub> receptors in GABA interneurons. This may eventually result in disinhibition of pyramidal neurons projecting to the VTA. A higher concentration of such compounds may overcome this effect, activating directly pyramidal 5-HT<sub>1A</sub> receptors and reducing the prefrontal excitatory output to dopaminergic neurons. Although such cellular difference in 5-HT<sub>1A</sub> receptor sensitivity remains to be established, pre-

vious reports are consistent with this possibility (Sprouse and Aghajanian, 1986, 1987; Beck *et al.*, 1992), perhaps because of a different expression level in different neuronal populations (Hoyer and Boddeke, 1993).

Recently, 5-HT<sub>2A</sub> receptors have been localized to both dopaminergic (about 20–40 percent of the population, according to different authors) and non-dopaminergic (putatively GABA-containing) neurons in the VTA (Cornea-Hébert *et al.*, 1999; Doherty and Pickel, 2000; Ikemoto *et al.*, 2000; Nocjar *et al.*, 2002). The 5-HT<sub>2A</sub> receptor subtype in the VTA may be of particular relevance to some psychiatric illnesses, in particular schizophrenia, since 5-HT<sub>2A</sub> receptor agonists such as LSD are potent hallucinogens, whereas atypical antipsychotic drugs are 5-HT<sub>2A</sub> receptor antagonists (Schmidt *et al.*, 1995; Meltzer *et al.*, 2003). From a functional point of view, it has been observed that the administration of 5-HT<sub>2A</sub> receptor ligands modulates dopaminergic transmission (Gobert and Millan 1999; Ichikawa *et al.*, 2001; Minabe *et al.*, 2001; Pehek *et al.*, 2001, 2002) and

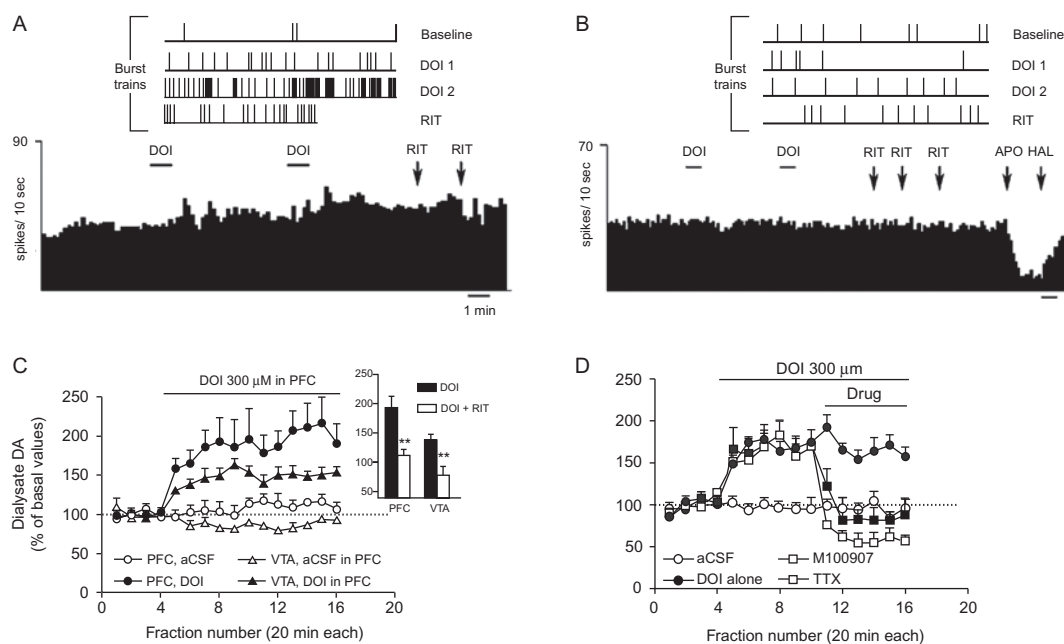

**Figure 4** Dose–response curves of the 5-HT<sub>1A</sub> receptor agonist BAY x 3702 (10–80 µg/kg, i.v.) on the firing rate (A) and burst firing (B) of VTA dopaminergic neurons in sham-operated and cortically transected rats. (C) The intravenous administration of BAY x 3702 (10, 20 and 40 µg/kg) elevated the extracellular concentration of dopamine in the VTA of sham-operated rats. The dotted line shows the effect in naïve and sham rats. This effect was totally abolished by cortical transection. (D) Sagittal section of a rat brain at the approximate lateral coordinate 3.4, taken from midline (Paxinos and Watson, 2005). The transection lesion is shown by arrows. \**P* < 0.05 versus baseline; <sup>a</sup>*P* < 0.05 versus controls. Data taken and redrawn from Díaz-Mataix *et al.* (2005), with permission.

recent results from our lab indicate that the activity of dopaminergic neurons of the VTA is under the excitatory control of 5-HT<sub>2A</sub> receptors located in the PFC (Figure 5; Bortolozzi *et al.*, 2005).

Besides 5-HT<sub>2A</sub> receptors, 5-HT<sub>2C</sub> receptors play also a prominent role in the regulation of dopaminergic function. Thus, 5-HT<sub>2C</sub> receptor agonists decrease the firing of VTA dopaminergic neurons (Prisco *et al.*, 1994; Di Giovanni *et al.*, 2000; Di Matteo *et al.*, 2000; Gobert *et al.*, 2000) and the release of dopamine in corticolimbic areas (Millan *et al.*, 1998; Di Giovanni *et al.*, 2000; Di Matteo *et al.*, 2000; Gobert *et al.*, 2000) through the activation of inhibitory, presumably GABAergic, interneurons (Di Giovanni *et al.*, 2001). In accord with this, 5-HT<sub>2C</sub> receptors have been found in GABAergic neurons within the VTA (Pompeiano *et al.*, 1994; Eberle-Wang *et al.*, 1997; Bubar and Cunningham, 2007). It appears that 5-HT<sub>2C</sub> receptors may exert a tonic inhibitory control of the activity of ascending dopamine neurons (Millan *et al.*,

1998; Di Matteo *et al.*, 1998, 1999; De Deurwaerdère and Spampinato, 1999; Di Giovanni *et al.*, 1999; Gobert *et al.*, 2000; Pozzi *et al.*, 2002), although this effect may depend on the activity of dopaminergic neurons (Pozzi *et al.*, 2002).

In addition to receptors belonging to the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families, a role for other 5-HT receptors in the control of the activity of dopamine neurons of the VTA has been suggested. Thus, the somatodendritic release of dopamine in the VTA is markedly increased by a 5-HT<sub>3</sub> receptor agonist, and slightly reduced by a 5-HT<sub>3</sub> receptor antagonist (Campbell *et al.*, 1996; Liu *et al.*, 2006; Rodd *et al.*, 2007). This is consistent with the finding that 5-HT<sub>3</sub> receptor antagonists reduce the number of spontaneously active VTA dopaminergic cells in rodents (Minabe *et al.*, 1991; Rasmussen *et al.*, 1991), and suggests that the somatodendritic release of dopamine in the VTA may be regulated by a local tonic excitatory action of 5-HT acting on 5-HT<sub>3</sub> receptors.

**Figure 5** (A) Representative example of a ventral tegmental area (VTA) dopaminergic neuron whose burst firing was increased by the local application of the 5-HT<sub>2A/2C</sub> receptor agonist DOI in the mPFC. Shown is the integrated firing rate histogram (abscissa, spikes/10s; ordinate, min). The four upper traces show burst trains in baseline conditions, after cortical DOI application (first and second doses) and after systemic ritanserin (RIT) administration. This unit had a baseline 1% of burst firing. The application of DOI (0.2 μl, 40 pmol, denoted by one 1-min horizontal bar) in the mPFC increased burst firing to 9 and 35% (first and second applications). The administration of ritanserin (1 + 1 mg/kg, i.v.) reduced burst firing to 14%. (B) Example of a VTA dopaminergic neuron insensitive to the application of DOI in the mPFC. The unit activity was suppressed by the administration of apomorphine (APO; 36 μg/kg, i.v.) and reversed by the subsequent administration of haloperidol (HAL; 0.4 mg/kg, i.v.). (C) In dual-probe microdialysis experiments, application of DOI in the mPFC increased dopamine (DA) release in the mPFC and VTA. Controls were perfused with artificial CSF (aCSF) for the entire experiment. Inset: reversal by ritanserin (300 μM, applied in the mPFC) of the elevation of dopamine release in the mPFC and VTA produced by the application of DOI (300 μM) in the mPFC. (D) In single probe experiments, the application of 300 μM DOI in the mPFC increased the local dopamine release. This effect was reversed by co-perfusion of 1 μM tetrodotoxin (TTX) and the selective 5-HT<sub>2A</sub> receptor antagonist M100907. Controls were perfused with aCSF for the entire experiment. Horizontal bars show the time of drug application. \*\**P* < 0.001 versus DOI alone. Data reproduced from Bortolozzi *et al.* (2005), with permission.

### ***Influence of dopamine receptors on brain serotonin***

In a reciprocal way, dopaminergic cells also control the activity of 5-HT neurons through projections from dopaminergic nuclei to the DR (Sakai *et al.*, 1977; Beckstead *et al.*, 1979; Kalén *et al.*, 1988; Peyron *et al.*, 1995; Kitahama *et al.*, 2000). In addition, a population of dopamine-containing neurons has been found within the boundaries of the DR (Hökfelt *et al.*, 1976; Descarries *et al.*, 1986; Geffard *et al.*, 1987; Kalén *et al.*, 1988; Hasue and Shammah-Lagnado, 2002; Lu *et al.*, 2006).

The activation of local dopamine D1 receptors with SKF 38393 does not alter 5-HT release in raphe nuclei (Ferré *et al.*, 1994; Adell and Artigas, 1999), which is consistent with the virtual absence of such receptors in these nuclei (Dawson *et al.*, 1988; Wamsley *et al.*, 1989). However, the systemic administration of the non-selective dopamine receptor agonist apomorphine enhances serotonergic cell firing and release in the DR, an effect fully antagonized by the D1 receptor antagonist SCH 23390 (Ferré *et al.*, 1994; Martín-Ruiz *et al.*, 2001a). This suggests that the activity of serotonergic neurons of the DR is partly under the control of D1 receptors located outside this nucleus. Furthermore, the effect of apomorphine is also attenuated by the D2/D3 receptor antagonist raclopride (Martín-Ruiz *et al.*, 2001a), which indicates an involvement of dopamine D2 receptors as well. The systemic administration of the dopamine D2 receptor agonist quinpirole slightly increases 5-HT cell firing and release in the DR (Martín-Ruiz *et al.*, 2001a). Nevertheless, the local application of quinpirole failed to alter the release of 5-HT in the DR and median raphe nucleus (MnR) (Adell and Artigas, 1999; Martín-Ruiz *et al.*, 2001a) or DR serotonergic cell firing (Martín-Ruiz *et al.*, 2001a). In summary, dopamine D1 and D2 receptors exert a facilitatory influence on the activity of serotonergic neurons in the DR. The differences between the results of local and systemic administration of the dopaminergic compounds seem to favor the view that these receptors are located outside the raphe nuclei. A possible location for such dopamine receptors is the substantia nigra, since the local perfusion of apomorphine in this region enhances the release of 5-HT in the DR (Martín-Ruiz *et al.*, 2001a).

### **Acetylcholine**

The existence of an interaction between serotonin and acetylcholine at the level of DR is based on several facts. First, there is anatomical evidence that the DR receives a cholinergic input from the adjacent laterodorsal tegmentum (LDTg) and the pedunculopontine tegmentum (PPTg) (Woolf and Butcher, 1989; Wang

*et al.*, 2000; Galindo-Charles *et al.*, 2008). Second, immunocytochemical studies have demonstrated the presence of postsynaptic  $\alpha 7$ - and  $\alpha 4\beta 2$ -containing nicotinic acetylcholine receptors (nAChRs) in serotonergic and non-serotonergic neurons of the DR (Seguela *et al.*, 1993; Bitner *et al.*, 2000; Bitner and Nikkel, 2002; Galindo-Charles *et al.*, 2008). Third, electrophysiological studies using *in vitro* preparations have also shown that nicotine stimulated DR 5-HT release (Mihailescu *et al.*, 2002). Fourth, the systemic administration of nicotine increased the concentration of serotonin not only in the DR but also in terminal areas of the brain, such as the cortex, striatum, hippocampus and hypothalamus (Seth *et al.*, 2002). Fifth, postsynaptic  $\alpha 7$ - and  $\alpha 4\beta 2$ -containing nAChRs in serotonergic and non-serotonergic neurons of the DR are fully functional as evidenced by electrophysiological studies using selective antagonists (Galindo-Charles *et al.*, 2008).

The activities of both cholinergic and serotonergic systems are elevated during arousal and wake states. However, in contrast to serotonergic cells of the DR, the majority of LDT and PPTg cholinergic neurons are highly active during both wakefulness and REM sleep (Steriade *et al.*, 1990a, 1990b). Furthermore, cholinergic LDT and PPTg neurons are tonically inhibited by 5-HT<sub>1A</sub> receptor agonists during the waking state, but not during REM sleep state (Thakkar *et al.*, 1998). This distinct interaction may have a fundamental physiological implication in terms of the maintenance of the waking state by the cholinergic input to the DR (Hobson *et al.*, 2000).

### **GABA**

Several experiments evidenced that serotonergic projection neurons and GABA-containing neurons present in the raphe nuclei mutually regulate each other's activity (Gallager and Aghajanian, 1976b; Forchetti and Meek, 1981). Serotonergic neurons of the raphe nuclei are under an inhibitory GABAergic influence not only from intrinsic GABA-containing cells (Belin *et al.*, 1979; Harandi *et al.*, 1987; Wang *et al.*, 1992) but also from the periaqueductal gray (Jolas and Aghajanian, 1997) and multiple distant sources (Gervasoni *et al.*, 2000). This is supported by a great number of GABAergic perikarya and nerve endings present in the DR and its vicinity (Nanopoulos *et al.*, 1982; Belin *et al.*, 1983; Harandi *et al.*, 1987; Stamp and Semba, 1995; Abellán *et al.*, 2000a).

Two are the GABA receptors involved in the regulation of serotonergic transmission – GABA<sub>A</sub> and GABA<sub>B</sub> receptors – and both subtypes have been found in the raphe nuclei (Bowery *et al.*, 1987; Chu *et al.*, 1990; Bischoff *et al.*, 1999; Lu *et al.*, 1999; Abellán *et al.*, 2000a, 2000b). GABA<sub>A</sub> receptors are expressed in 5-HT cells (Mennini

*et al.*, 1986; Gao *et al.*, 1993), whereas GABA<sub>B</sub> receptors are present both in serotonergic neurons (Wirtshafter and Sheppard, 2001; Varga *et al.*, 2002; Serrats *et al.*, 2003) and, as autoreceptors, in GABA-containing neurons (Waldmeier *et al.*, 1988; Bowery, 1993; Serrats *et al.*, 2003). From a physiological viewpoint, it is well known that GABA inhibits DR 5-HT cell firing (Gallager and Aghajanian, 1976b; Wang and Aghajanian, 1977; Levine and Jacobs, 1992; Gervasoni *et al.*, 2000) as well as 5-HT synthesis and turnover (Forchetti and Meek, 1981; Nishikawa and Scatton, 1985), which results in a suppression of 5-HT release in forebrain (Becquet *et al.*, 1990; Abellán *et al.*, 2000b). In microdialysis studies, the local application of GABA did not alter 5-HT release in the DR (Abellán *et al.*, 2000b). However, the GABA<sub>A</sub> receptor agonist muscimol decreases the release of 5-HT in the DR (Tao *et al.*, 1996). Different influence of the GABAergic input in the raphe nuclei might explain such a discrepancy. The GABAergic tone on 5-HT neurons and the release of GABA in the DR changes across the sleep–wake cycle, being minimal during light conditions and increasing with sleep (Jacobs and Fornal, 1991; Nitz and Siegel, 1997; Gervasoni *et al.*, 2000). Thus, the different waking state of the animals, such as light conditions (Abellán *et al.*, 2000a, 2000b) or darkness (Tao *et al.*, 1996), could account for these inconsistent observations. The local application of the GABA<sub>A</sub> receptor antagonist bicuculline elevates 5-HT release in the DR (Tao *et al.*, 1996), which would suggest that GABAergic transmission exerts a tonic inhibition on 5-HT release in the DR through GABA<sub>A</sub> receptors. However, the fact that GABA inhibits 5-HT cell firing but not release suggests that at least a portion of 5-HT release in the DR does not depend on serotonergic cell firing.

Conflicting results have also been reported with respect to the influence of GABA<sub>B</sub> receptors on serotonergic transmission. Thus, both systemic and local administration of baclofen (a selective GABA<sub>B</sub> receptor agonist) were shown to increase (Abellán *et al.*, 2000a, 2000b) or decrease (Tao *et al.*, 1996) 5-HT release in the raphe nuclei. On the other hand, it seems that baclofen activates preferentially presynaptic GABA<sub>B</sub> receptors in the DR, as indicated by a pre- versus postsynaptic EC<sub>50</sub> ratio of ~20 (Abellán *et al.*, 2000b). This is in good concordance with its actions in terminal areas (Howe *et al.*, 1987; Davies *et al.*, 1990). Hence, in the presence of an active GABAergic input onto 5-HT neurons (light conditions, see above), baclofen would remove the tonic GABA<sub>A</sub> input through its predominant activation of presynaptic GABA<sub>B</sub> receptors. In this manner, it might increase 5-HT release through an effect resembling that of bicuculline – i.e., GABA<sub>A</sub> disinhibition. In contrast, during darkness (a condition associated with a low GABAergic input onto

5-HT neurons) a direct inhibitory effect of baclofen on 5-HT neurons would prevail, thus resulting in a reduction of 5-HT release (Tao *et al.*, 1996). Furthermore, it is worth noting that GABA<sub>B</sub> receptor antagonists are without effect in either light or dark conditions (Tao *et al.*, 1996; Abellán *et al.*, 2000a). Therefore, it appears that GABA<sub>B</sub> receptors do not exert a tonic control on the release of 5-HT in the raphe nuclei.

The inhibitory GABAergic control of serotonergic neurons of the raphe nuclei is also under the influence of 5-HT receptors. Thus, in addition to the autoreceptor role of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor subtypes localized to serotonergic neurons, these receptors are also expressed in GABAergic interneurons within the raphe nuclei (Serrats, Mengod and Cortés, unpublished results). Consequent with the inhibitory function of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors, it has been shown that their stimulation by serotonin reduced the release of GABA *in vitro* (Bagdy *et al.*, 2000; see Harsing, 2006 for review).

Electrophysiological studies first suggested the presence of 5-HT<sub>2C</sub> receptors on GABA-containing neurons, within or in the vicinity of the DR (Liu *et al.*, 2000). This has been recently supported by the observation that 5-HT<sub>2C</sub> receptor mRNA existed in most GABAergic cells, recognized by the presence of glutamic acid decarboxylase mRNA, but was not detected in serotonin transporter mRNA-containing cells in the DR (Serrats *et al.*, 2005). Such 5-HT<sub>2C</sub> receptor-positive GABAergic neurons were mainly located in the intermediolateral and lateral portions of the DR and provide an anatomical support to the proposed negative-feedback loop involving reciprocal connections between GABAergic interneurons bearing 5-HT<sub>2C</sub> receptors and 5-HT neurons in the DR (Liu *et al.*, 2000; Boothman *et al.*, 2003; Boothman and Sharp, 2005). A possible role of DR 5-HT<sub>2A</sub> receptors in this negative-feedback loop has also been suggested (Boothman *et al.*, 2003). Nevertheless, although 5-HT<sub>2A</sub> receptor messenger RNA was detected in the DR, 5-HT<sub>2A</sub> receptor immunoreactivity in this nucleus was not (Wright *et al.*, 1995; Cornea-Hébert *et al.*, 1999; Fay and Kubin, 2000). For this reason, the influence of 5-HT<sub>2A</sub> receptor activation on DR serotonergic neurons may be mediated by an action on 5-HT<sub>2A</sub> receptors located on distant sites, most likely the medial prefrontal cortex (Martín-Ruiz *et al.*, 2001b).

## Glutamate

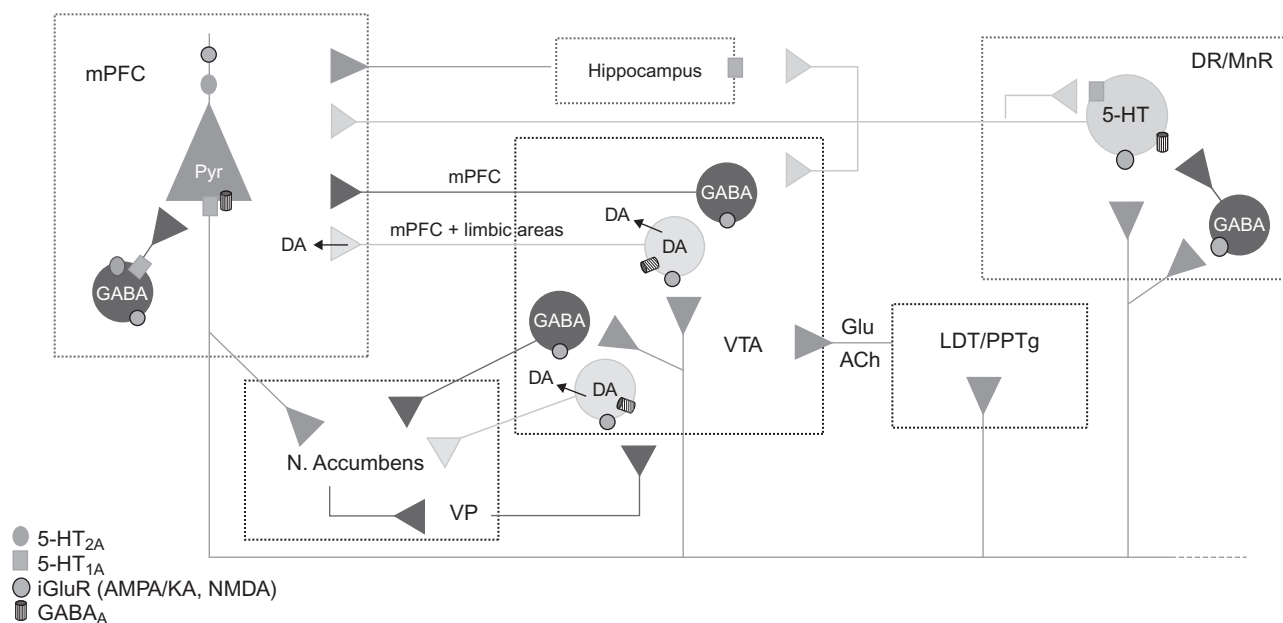

Numerous electrophysiological and biochemical studies have evidenced a strong glutamatergic input to the DR (Pan and Williams, 1989; Tao and Auerbach, 1996; Tao *et al.*, 1997; Celada *et al.*, 2001; Puig *et al.*, 2003;

Amargós-Bosch *et al.*, 2004; Gabbott *et al.*, 2005), which originates in the lateral habenula, periaqueductal gray, lateral hypothalamus and mPFC (Aghajanian and Wang, 1977; Kalén *et al.*, 1985, 1986; Hajós *et al.*, 1998; Peyron *et al.*, 1998; Vertes, 2004). Ionotropic glutamate receptors (iGluR) can be divided in three subtypes, namely AMPA, kainate and *N*-methyl-D-aspartate (NMDA) receptors, and each of them appears to be responsible for the glutamatergic stimulation of serotonergic cells in the DR. Thus, intracellular recordings in midbrain slice preparations have identified AMPA/kainate- and NMDA-mediated currents in DR 5-HT neurons (Pan and Williams, 1989). Accordingly, the activation of these neurons *in vivo* elicited by electrical stimulation of the mPFC is abolished by AMPA/kainate and NMDA receptor antagonists (Celada *et al.*, 2001). Likewise, *in vivo* microdialysis studies gives support to the involvement of the three iGluRs in the control of 5-HT release in the DR. Thus, kainate, which binds to both AMPA and kainate receptors (Hall *et al.*, 1994), elevates 5-HT release in DR in an impulse-dependent manner (Tao *et al.*, 1997; Tao and Auerbach, 2000). AMPA can also increase extracellular 5-HT in DR, but only if the rapid desensitization of the receptor is prevented (Tao *et al.*, 1997). The effects of AMPA/kainate receptor agonists in DR can be blocked by kynurenate or DNQX (Tao *et al.*, 1997), which by themselves fail to alter 5-HT release (Tao *et al.*, 1997). Similarly to AMPA/kainate receptor agonists, NMDA evokes an increase of 5-HT release in the DR *in vivo* (Tao and Auerbach, 1996) and in midbrain primary cultures (Becquet *et al.*, 1993). The effect of NMDA can be antagonized by simultaneous perfusion of competitive or non-competitive NMDA receptor antagonists (Tao and Auerbach, 1996, 2000). In contrast to iGluRs, there is a lack of information about the role of mGluRs in the control of the activity of serotonergic cells within the DR, probably because the scanty presence of these receptors in the raphe nuclei (Shigemoto and Mizuno, 2000).

#### ***Projection from prefrontal cortex to raphe nuclei: crossroad of multiple receptors and transmitters***

Special attention must be paid to the projection from the mPFC to the DR (Hajós *et al.*, 1998; Peyron *et al.*, 1998; Vertes, 2004). The axons of 5 percent of pyramidal neurons located in layer V of mPFC project to DR (Gabbott *et al.*, 2005) and tightly control the activity of serotonergic cells of this nucleus (Hajós *et al.*, 1998; Celada *et al.*, 2001; Martín-Ruiz *et al.*, 2001b). Furthermore, this influence is dependent on the array of different receptors of multiple transmitters present in pyramidal neurons as well as GABAergic interneurons that control cortical circuits.

Due to the connectivity of the mPFC with brainstem monoaminergic nuclei (Figure 6), this brain region constitutes a crossroads at which several transmitters, such as glutamate, GABA, 5-HT, dopamine and noradrenaline, interact. Therefore, the main excitatory afferents to the mPFC (mediodorsal nucleus of the thalamus and hippocampus) as well as the cortical output can be modulated in turn by serotonergic pathways arising from the midbrain raphe nuclei. These multiple interactions integrate excitatory and inhibitory inputs, and are of paramount importance for a correct operation of higher brain functions. As a rule, the stimulation of excitatory and inhibitory receptors located in pyramidal neurons will lead, respectively, to an increase or decrease of 5-HT cell firing and/or release. However, a great number of receptors have a dual location in both pyramidal cells and GABAergic interneurons, and the final response of serotonergic cells will depend on a balance of the actions of different transmitters on their respective receptors present in both cellular types. Therefore, the extracellular concentration of 5-HT in the mPFC can be regarded as an *in vivo* neurochemical index of the pyramidal influence on ascending midbrain 5-HT neurons. This experimental approach is based on several observations. First, as mentioned above, anatomical, electrophysiological and neurochemical studies indicate the presence of a very close reciprocal relationship between the mPFC and the midbrain raphe nuclei. Thus, the electrical stimulation of the mPFC elicited profound changes in most DR 5-HT neurons and *vice versa* (Hajós *et al.*, 1998; Celada *et al.*, 2001; Puig *et al.*, 2005). As a consequence, the electrical stimulation of the mPFC increased 5-HT release in the DR (Celada *et al.*, 2001). Second, the activation of excitatory (5-HT<sub>2A</sub>,  $\alpha_1$ -adrenergic, AMPA) or inhibitory (5-HT<sub>1A</sub>,  $\mu$ -opioid, mGluR2/3) receptors in mPFC increased and decreased, respectively, the local 5-HT release and – when examined – the firing of 5-HT neurons and 5-HT release in the DR (Celada *et al.*, 2001; Martín-Ruiz *et al.*, 2001b; Amargós-Bosch *et al.*, 2003, 2004; Bortolozzi *et al.*, 2003; Puig *et al.*, 2003). Similar results have been obtained by stimulating mPFC pyramidal neurons through a disinhibition of the thalamocortical pathway (Puig *et al.*, 2003; Amargós-Bosch *et al.*, 2007). Another 5-HT receptor, namely 5-HT<sub>4</sub> receptor, has been recently shown to exert a facilitatory influence on a subpopulation of DR 5-HT neurons (Lucas and Debonnel, 2002). Furthermore, this 5-HT<sub>4</sub>-dependent facilitatory control on DR 5-HT neurons stems from the mPFC (Lucas *et al.*, 2005) and appears to be accounted for by a desensitization of 5-HT<sub>1A</sub> autoreceptors in the DR (Lucas *et al.*, 2007). Most importantly, such an effect is achieved after only a 3-day treatment with a 5-HT<sub>4</sub> receptor agonist. Thus, these findings suggest that 5-HT<sub>4</sub> receptor agonists might be regarded as a new class of

**Figure 6** Anatomical and functional relationship between the mPFC, the VTA, and the dorsal and median raphe nuclei (DR/MnR). Pyramidal neurons of the mPFC project directly to mesocortical (but not mesoaccumbal) dopamine (DA) neurons, closing an mPFC-VTA circuit. GABAergic cells in the VTA project to mPFC and limbic areas as well. The mPFC may also modulate the activity of VTA neurons indirectly, through the basal ganglia circuit (e.g., mPFC nucleus accumbens ventral pallidum (VP) pathway) or through afferents to the LDT/PPTg. Likewise, the mPFC is reciprocally connected with the DR/MnR. Pyramidal neurons of the mPFC project to raphe 5-HT and GABA neurons and modulate their activity. In turn, 5-HT neurons modulate the activity of pyramidal cells in the mPFC through various receptors, in particular 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors, which are expressed by pyramidal and GABAergic neurons. The pharmacological activation of these receptors in the mPFC has been shown to modulate 5-HT neuron activity and terminal 5-HT release via descending afferents to the midbrain. In addition, to the mPFC, 5-HT<sub>1A</sub> receptors are densely expressed in the DR/MnR (autoreceptors) and in areas projecting to the mPFC, such as the hippocampal formation. Direct 5-HT afferents to the VTA may also be involved in the control of DA neurons by other 5-HT receptors, notably the 5-HT<sub>2C</sub> subtype, present in GABAergic neurons of the VTA. Abbreviations: Glu, glutamate; Pyr, pyramidal neuron; Ach, acetylcholine; N. Accumbens, nucleus accumbens; iGluR, ionotropic glutamate receptor; KA, kainic acid. antidepressant drugs with a rapid onset of action. Taken together, all these effects are likely driven by changes in the excitatory output of the mPFC to DR and the subsequent change in serotonergic activity (Celada *et al.*, 2001; Martín-Ruiz *et al.*, 2001b).

The projections of the mPFC to other brainstem nuclei such as the VTA and the locus coeruleus underscore the importance of the modulation of the activity of the pyramidal cell in the mPFC by 5-HT receptors. For example, our research group has shown that 5-HT<sub>1A</sub> receptors in the mPFC are deeply involved in the modulation of dopaminergic activity because the 5-HT<sub>1A</sub> agonist, BAY x 3702, failed to alter dopaminergic cell activity or dopamine release in the VTA in cortically transected rats (Díaz-Mataix *et al.*, 2005). This complex interplay confers a crucial importance for the interactions between glutamate and other transmitter systems at the level of mPFC, and may help to elucidate the mechanisms involved in the elevation of mesocortical dopamine release produced by atypical antipsychotics.

# Serotonergic Regulation of Rhythmical Activity of the Brain, Concentrating on the Hippocampus

Robert P. Vertes\*

*Center for Complex Systems and Brain Sciences, Florida Atlantic University, Boca Raton, Florida*

**Abstract:** The dorsal (DRN) and median raphe (MRN) nuclei are the major serotonin-containing nuclei of the brainstem, with extensive projections to the forebrain. With a few exceptions, DRN and MRN give rise to separate, non-overlapping sets of projections to the forebrain. The MRN is mainly a midline/paramidline system with fibers primarily distributing to medial parts of the hypothalamus and thalamus, the medial basal forebrain, the septum and the hippocampus. By contrast, DRN fibers distribute to most of the remaining regions of the forebrain, including the substantia nigra, the lateral hypothalamus, the amygdala, and widespread regions of the basal forebrain and cortex. DRN and MRN essentially only send common projections to the midline and intralaminar thalamus. These differential projections undoubtedly reflect functional differences of the two systems. There are two major states of the hippocampal electroencephalogram (EEG), the theta and non-theta states, and the non-theta state has been further divided into large and small irregular activity, LIA and SIA, respectively. Non-theta states of the hippocampal EEG appear to be directly controlled by serotonergic neurons of MRN that exert desynchronizing actions on the hippocampal EEG (or blockade of theta) by disrupting the discharge of theta rhythmically firing neurons of the septum and/or the hippocampus. MRN stimulation desynchronizes the hippocampal EEG, MRN lesions produce constant, uninterrupted theta, and a network of neurons has been identified in MRN with discharge characteristics related to the hippocampal EEG. This includes populations of 5-HT projection and non-projection neurons and GABAergic interneurons that interact to modulate the hippocampal EEG. The theta rhythm serves a well-recognized role in memory-processing functions of the hippocampus. Accordingly, it seems that by blocking theta (or desynchronizing the hippocampal EEG) 5-HT MRN cells may suppress or temporarily suspend memory-processing functions of the hippocampus. The MRN may be an important part of a system of connections that directs the hippocampus to essentially disregard insignificant environmental events. The DRN contains relatively significant numbers of serotonergic and GABAergic cells that fire rhythmically phase-coupled to theta. These DRN cells may provide theta synchronous input to several DRN targets known to exhibit theta rhythmicity (anterior thalamus, amygdala, striatum and prefrontal cortex), possibly to coordinate their activity during theta states or conditions.

**Keywords:** dorsal and median raphe nuclei, septum, hippocampus, theta rhythm, electroencephalogram, memory.

## Serotonergic systems of the brainstem

It is well established that the brainstem contains discrete groups of serotonin-containing (5-hydroxytryptamine, 5-HT) neurons, extending from the caudal medulla to the rostral midbrain. It has further been shown that the axonal processes of these cells are extensive, distributing

to structures throughout the neuroaxis. As would be expected from this widespread distribution, 5-HT cells participate in a range of functions which may, in part, be mediated through a serotonergic modulation of rhythmical activities.

In their original report in the rat, Dalhstrom and Fuxe (1964) identified nine serotonin-containing cell groups of the brainstem which they termed B1–B9. With the exception of B9, these 5-HT containing nuclei are located on the midline and, as such, were designated raphe nuclei; *raphe* meaning seam, or in this context the line of

---

\*E-mail: vertes@ccs.fau.edu

junction (midline) of the two halves of the brainstem. With the possible exclusion of B9, the alpha-numerical designations for the raphe nuclei have been replaced by names which reflect their anatomical location or characteristics, such as B1, raphe pallidus; B2, raphe obscurus; B3, raphe magnus; B5, raphe pontis; B7, dorsal raphe nucleus (DRN); and B8, median raphe nucleus (MRN) (Halliday *et al.*, 1995; Harding *et al.*, 2004).

In addition to these cell groups, recently developed histochemical procedures (Arita *et al.*, 1993; Vertes and Crane, 1997) have revealed the presence of relatively significant numbers of 5-HT neurons lateral to the midline within the medulla and the pons/midbrain. Those of the medulla primarily extend laterally from nucleus raphe magnus along the floor of the rostral medulla, while 5-HT cells of the pons/midbrain (outside of B9) stretch laterally from the DRN across the dorsal pontine tegmentum and ventrolaterally within the pontomesencephalic reticular formation (RF) (Vertes and Crane, 1997). For the most part, the caudal raphe nuclei (B1, B2, B3) give rise to descending projections to the lower brainstem and spinal cord, while the rostral raphe nuclei, particularly DRN and MRN, project widely throughout the upper brainstem and forebrain (Vertes and Martin, 1988; Vertes, 1991; Jacobs and Azmitia, 1992; Morin and Meyer-Bernstein, 1999; Vertes *et al.*, 1999; Aznar *et al.*, 2004).

### Serotonergic neurons of the dorsal and median raphe nuclei

As is well recognized, the dorsal and median raphe are densely populated with serotonergic neurons. At the midbrain, 5-HT cells of DRN are fairly concentrated along the midline, whereas further caudally they remain densely packed medially, but also extend laterally from the core of DRN to its lateral 'wings' (Figure 1). Serotonergic cells of DRN are typically large (30–40  $\mu\text{m}$ ), fusiform in shape, stain darkly for 5-HT and contain about four or five primary dendrites radiating from the cell body.

By comparison with DRN, there are considerably fewer 5-HT containing neurons in MRN. As shown in Figure 1, serotonergic MRN cells are dispersed fairly evenly throughout the nucleus. Those located dorsally in MRN are predominantly small (10–12  $\mu\text{m}$ ), oval, and stain lightly for 5-HT, whereas 5-HT cells of the ventral MRN are medium-sized (15–22  $\mu\text{m}$ ) and either oval or spindle-shaped. The dendrites of the oval cells are short (10–20  $\mu\text{m}$ ) and coarse, while those of the spindle-shaped neurons are generally long (40–150  $\mu\text{m}$ ).

Surprisingly, with the degree of interest in 5-HT systems, few studies have quantified numbers of 5-HT

**Figure 1** Lightfield photomicrograph of a transverse section through the upper brainstem showing 5-HT immunostained cells in the dorsal raphe nucleus (DR) (including the lateral wings of DR), the median raphe nucleus (MR) and the suprallemniscal nucleus (SLN/B9). Abbreviations: AQ, cerebral aqueduct; ml, medial lemniscus; RPO, nucleus pontis oralis.

cells in raphe nuclei (Lowry *et al.*, 2008). Early studies estimated the number of 5-HT cells in MRN at ~1100 cells (Descarries *et al.*, 1982) and in DRN at 11,500 cells (Moore *et al.*, 1978). More recently, we reported the following values for the rat: 5-HT cells in DRN = 15,191; in MRN = 4114; in the suprallemniscal nucleus (or B9) = 4571 and in the pontomesencephalic reticular formation = 1948 (Vertes and Crane, 1997; Vertes and Linley, 2008).

### Ascending projections of the dorsal raphe nucleus

It is well documented that DRN fibers distribute widely throughout the neuroaxis (Vertes, 1991; Jacobs and Azmitia, 1992; Halliday *et al.*, 1995; Harding *et al.*, 2004). With some differences among reports, several early studies, using older tracing techniques, showed that DRN strongly innervates several forebrain sites, including the lateral hypothalamus, the midline and intralaminar nuclei of the thalamus, parts of the amygdala, the dorsal

and ventral striatum, the septum, the hippocampus, and widespread regions of the cortex (Azmitia and Segal, 1978; Moore *et al.*, 1978). More recent examinations of DRN projections (Vertes, 1991; Vertes and Kocsis, 1994; Morin and Meyer-Bernstein, 1999; Waselus *et al.*, 2006; Kanno *et al.*, 2008), primarily using the anterograde tracer *Phaseolus vulgaris* leucoagglutinin (PHA-L), confirmed some earlier findings and described additional ones as follows.

Specifically, it has been shown that the main subcortical targets of DRN are the midbrain/diencephalic central gray, the ventral tegmental area (VTA), the substantia nigra-pars compacta (SNc), and the lateral (LHy) and supramammillary (SUM) nuclei of hypothalamus; the anterior (anteroventral and anteromedial), lateral (lateral dorsal and lateral posterior), mediodorsal, midline and intralaminar, and lateral geniculate nuclei (LGN) of the thalamus; the central, lateral, basolateral, basomedial and amygdalo-piriform transition zone of the amygdala; and the nucleus accumbens (ACC), dorsal striatum (caudate-putamen, CP), bed nucleus of stria terminalis (BST), lateral septum (LS), lateral preoptic area (LPO), substantia innominata (SI), magnocellular preoptic area (MgPO), ventral pallidum (VP), endopiriform nucleus (EN) and claustrum (CLA) of the basal forebrain (Vertes, 1988, 1991; Morin and Meyer-Bernstein, 1999).

The main cortical targets of DRN are the entorhinal (EC), piriform, agranular insular (dorsal, ventral and posterior divisions), lateral agranular (frontal) cortex, medial orbital (MO) and medial prefrontal cortex (mPFC) (Vertes, 1991; Vertes and Linley, 2008). The latter includes the medial agranular (AGm), anterior cingulate (AC), prelimbic (PL) and infralimbic (IL) cortices. DRN distributes moderately to the hippocampal formation (HF).

#### ***DRN projections to the dopaminergic (DA) system: projections to dopaminergic cells and to their sites of termination***

It is well recognized that the serotonergic system interacts with and influences dopaminergic systems of the brain (Kapur and Remington, 1996; Di Matteo *et al.*, 2002). DRN fibers distribute significantly to major DA cell groups of the midbrain – the substantia nigra, pars compacta (SNc) and ventral tegmental area (VTA). In a complementary manner, DRN projects to main SNc and VTA targets; namely, to the basal nuclei of the amygdala, dorsal and ventral (nucleus accumbens) striatum and BST, and widely throughout the frontal cortex to the agranular insular, mPFC, and orbital cortices. In effect,

DRN is positioned to influence the origins and terminal destinations of the nigrostriatal (from SNc) and mesolimbic (from VTA) systems.

#### ***DRN projections to the thalamus***

The primary destinations of DRN fibers to the thalamus are the anteromedial, anteroventral, mediodorsal (MD), LGN and the midline and intralaminar nuclei of the thalamus (Pechanski and Besson, 1984; Vertes, 1991; Morin and Meyer-Bernstein, 1999; Krout *et al.*, 2002; McKenna and Vertes, 2004). The latter group mainly includes the reuniens (RE), rhomboid (RH), interanteromedial (IAM), paratenial (PT) and paraventricular (PV) nuclei of the midline thalamus, and the central medial (CEM), central lateral (CL), paracentral (PC) and parafascicular nuclei of the intralaminar thalamus. Accordingly, with the possible exception of the lateral geniculate nucleus (LGN), DRN projects heavily to a subset of thalamic nuclei that have been characterized as the ‘limbic thalamus’, based on their diverse and widespread afferents from the brainstem/diencephalon and selective projections to the limbic forebrain (Vertes, 2006; Vertes *et al.*, 2006; Vertes and Hoover, 2008). DRN/serotonergic input to the ‘limbic thalamus’ would appear to be important for such processes as arousal, attention and affect (Bentivoglio *et al.*, 1991; Van der Werf *et al.*, 2002; Kirouac *et al.*, 2006; Vertes, 2002, 2004, 2006; Hsu and Price, 2009).

#### ***DRN projections to the basal forebrain***

DRN fibers distribute widely over the basal forebrain (BF) to the BST, LS, and dorsal and ventral striatum, and along the floor of the basal forebrain to the substantia innominata (SI), ventral pallidum (VP), and lateral preoptic area (Vertes, 1991; Morin and Meyer-Bernstein, 1999). As will subsequently be discussed in greater detail, both DRN and MRN project strongly to the septum, but to separate regions thereof. DRN distributes substantially to regions of the basal forebrain that contain dense populations of cholinergic (ACh) neurons: the magnocellular preoptic nucleus (MgPO), SI and VP (Vertes, 1988; Gasbarri *et al.*, 1999; Zaborszky, 2002). As is well-established, ACh-containing fibers of the basal forebrain project widely throughout the cortex (Rye *et al.*, 1984; Woolf *et al.*, 1984; Luiten *et al.*, 1987) and reportedly serve an important role in behavioral/EEG arousal (Zaborszky, 2002; Jones, 2004; Sarter *et al.*, 2005) as well as in cognitive functions (Cassel and Jeltsch, 1995; Jeltsch-David *et al.*, 2008), DRN projections to these sites (as well as those to

the limbic thalamus and cortex) would appear to modulate processes of arousal/attention.

### ***DRN projections to the cortex***

Similar to the thalamus, the foremost targets of DRN fibers to the cortex are to parts of the 'limbic cortex', including the medial orbital, agranular insular, piriform, mPFC (AC, PL, IL) and entorhinal cortices. DRN distributes much less abundantly to associational, somatosensory, and special sensory areas of the cortex. The marked DRN projections to 'limbic cortices' are consistent with global 5-HT actions on the forebrain, including a significant influence on affect and mood (Hensler, 2006; and this volume).

### **Ascending projections of the median raphe nucleus**

Unlike the widespread distribution of DRN fibers to the forebrain, MRN projects to a much more restricted group of forebrain structures (Vertes and Martin, 1988; Morin and Meyer-Bernstein, 1999; Vertes *et al.*, 1999; Kanno *et al.*, 2008). MRN fibers predominantly distribute to midline structures of the forebrain – including medial regions of the hypothalamus, thalamus and basal forebrain – as well as to the hippocampus. In effect, the MRN represents a midline/paramidline system of connections. Primary forebrain targets of MRN are the interpeduncular nucleus (IP), VTA, medial mammillary nucleus, supramammillary nucleus (SUM), posterior nucleus of the hypothalamus (PH), the dopamine-cell containing A13 region of medial zona incerta (ZI), the parafascicular, reuniens, mediodorsal, central medial, paracentral and central lateral nuclei of the midline/intralaminar thalamus, the lateral habenula, the suprachiasmatic nucleus (SCN), the vertical and horizontal limbs of diagonal band nuclei, the medial septum (MS) and the hippocampus. Overall, MRN projections to the (neo) cortex are light, and essentially restricted to the perirhinal, entorhinal and parts of the prefrontal cortices.

In contrast to DRN, MRN sends some fibers to VTA, but mainly targets the A13 group of the medial zona incerta. Among putative functions, DA cells of the medial ZI have been implicated in the release of gonadotropins; MRN stimulation enhances the secretion of gonadotropins (James *et al.*, 1987; Morello *et al.*, 1989).

Although there is some overlap of MRN and DRN projections to the hippocampus, MRN distributes much more heavily than DRN to the hippocampus. MRN fibers permeate all parts of the dorsal and ventral HF, terminating densely in the outer molecular layer (stratum lacunosum-moleculare) of CA1 and CA3 of Ammon's horn and

within the inner molecular and granule cell layers of the dentate gyrus (DG).

The pronounced MRN projections to the septum and hippocampus suggest that MRN may distribute to both sites via axon collaterals originating from a common group of cells. We recently examined this, using fluorescent retrograde tracers (McKenna and Vertes, 2001), and found that: (1) approximately 8–12 percent of MRN neurons were double-labeled (collateral projections to medial septum and hippocampus); (2) double-labeled cells were predominately located in the rostral MRN; and (3) considerably more double-labeled cells were present in MRN than DRN. This suggests that a discrete population of MRN neurons (mainly of the rostral MRN) may simultaneously influence the septum and hippocampus.

### **Differential DRN and MRN projections**

As may be apparent from the foregoing, with few exceptions, the dorsal and median raphe nuclei distribute to separate, essentially non-overlapping, sites in the forebrain. As described, MRN is predominately a midline/para-midline system of projections, with pronounced projections to the medial hypothalamus and thalamus, and to the septum and hippocampus. With the exception of modest projections to the perirhinal and entorhinal cortices, MRN sends few projections to other (lateral) parts of the forebrain.

By contrast, DRN fibers distribute to most of the remaining regions of the forebrain (not served by MRN), primarily including the substantia nigra, the lateral hypothalamus, the amygdala, and widespread regions of the basal forebrain and cortex. DRN and MRN essentially only send common (overlapping) projections to the midline and intralaminar thalamus. Both nuclei distribute to the septum and the nucleus accumbens, but to different (non-overlapping) parts of these structures. In effect, then, the raphe/5-HT innervation of the forebrain is shared by MRN and DRN. These differential projections undoubtedly reflect functional differences of the two systems.

### **Differential serotonergic DRN and MRN projections to the septum and hippocampus**

We recently examined the possible differential distribution of 5-HT DRN and MRN fibers to the forebrain, concentrating on the septum and hippocampus, by initially determining the overall patterns of distribution of 5-HT fibers to the forebrain and then comparing these patterns to those seen following selective 5-HT lesions of MRN (with 5,7-dihydroxytryptamine (5,7-DHT) or DRN (with

**Figure 2** Lightfield photomicrographs of transverse sections through the rostral forebrain showing the distribution of 5-HT fibers within the septal region visualized with an antisera for the serotonin transporter protein (SERT), in (A) a naive rat, and (B) a PCA lesioned rat. Note a complete loss of 5-HT axons throughout the dorsal and ventral lateral septum (LS) in the PCA lesioned rat, while fibers remain intact in the medial septum (MS) and the nucleus of diagonal band, vertical division (DBv). Scale bar: 500  $\mu$ m.

*p*-chloroamphetamine (PCA)) (Vertes *et al.*, 2007). In the following, we show representative samples of normal patterns of 5-HT immunolabeling in the septum and hippocampus, and patterns observed following the selective destruction of 5-HT MRN or DRN cells.

Figure 2A shows the normal pattern of 5-HT innervation of the septum, and the pattern seen following peripheral injections of PCA (Figure 2B). As depicted in Figure 2A,

5-HT immunolabeled fibers fill the lateral and medial septum (MS) with greatest density in MS and the vertical limb of the diagonal band nuclei (DBv). Following PCA treatment which selectively destroys 5-HT DRN fibers (Mamounas and Molliver, 1988; Mamounas *et al.*, 1991), there is a complete loss of 5-HT axons dorsoventrally throughout the lateral septum, while those of MS and DBv remain intact (Figure 2B). This is consistent with

**Figure 3** Lightfield photomicrographs of transverse sections through the dorsal hippocampus showing the distribution of 5-HT fibers within the hippocampus visualized with an antisera for the serotonin transporter protein (SERT), in (A) a naive rat, and (B) a 5,7-DHT MR lesioned rat. Note the heavy concentration of 5-HT fibers throughout the hippocampus in the naive rat (A) and a dramatic loss of 5-HT fibers following an injection of 5,7-DHT in MR (B). Abbreviations: CA1, CA1 field of Ammon's horn of the dorsal hippocampus; DG, dentate gyrus of hippocampus; LD, laterodorsal nucleus of the thalamus; sIm, stratum lacunosum-moleculare. Scale bar: for (A), 500  $\mu$ m; for (B), 625  $\mu$ m.

selective MRN projections to MS and DRN projections to the intermediate LS.

Figure 3A shows the normal pattern of distribution of 5-HT fibers to the hippocampal formation (HF), and the patterns seen following 5,7-DHT injections into MRN (Figure 3B). As depicted in Figure 3A, 5-HT fibers distribute heavily throughout the hippocampus, with a particularly dense concentration within the stratum lacunosum-moleculare (slm) of CA1, stratum oriens, pyramidal, and radiatum of CA2/CA3, and the polymorphic layer of the upper blade of the dentate gyrus. As demonstrated in Figure 3B, there is a dramatic loss of 5-HT fibers throughout the hippocampus following a 5,7-DHT injection in MRN. This is consistent with the demonstration that HF receives its main raphe (and 5-HT) input from MRN.

### **Role of the median raphe (MRN) nucleus in the control of non-theta states of the hippocampal electroencephalogram (EEG) – or hippocampal EEG desynchronization**

An extensive body of evidence indicates that the MRN serves a direct role in controlling the non-theta (or desynchronized) state of the hippocampal EEG. It was demonstrated early on that MRN stimulation desynchronized the hippocampal EEG (Macadar *et al.*, 1974; Assaf and Miller, 1978; Yamamoto *et al.*, 1979; Vertes, 1981), and that MRN lesions produced uninterrupted theta, independent of behavior (Maru *et al.*, 1979; Yamamoto *et al.*, 1979). It was further shown that the desynchronizing effects of MRN on the hippocampal EEG were mediated by serotonergic MRN neurons. Specifically, Assaf and Miller (1978) demonstrated that the disruptive effect of MRN stimulation on septal pacemaking cells and the hippocampal EEG was blocked by pre-treatment with the 5-HT synthesis inhibitor p-chlorophenylalanine (PCPA), which produced a 60–80 percent depletion of forebrain serotonin, while Yamamoto *et al.* (1979) reported that ongoing theta produced by MRN lesions could be temporarily disrupted by injections of the serotonin precursor L-5-hydroxytryptophan (L-5-HTP). More recently, we demonstrated that injections of various substances into MRN that either suppressed 5-HT MRN neurons (5-HT<sub>1A</sub> autoreceptor agonists or GABA agonists) or reduced excitatory drive to them (excitatory amino acid antagonists) produced theta at short latencies (1–2 min) and for long durations (20–80 min) (Kinney *et al.*, 1994, 1995, 1996; Vertes *et al.*, 1994). In a similar manner, Varga *et al.* (2002) identified GABA<sub>B</sub> receptors on serotonergic neurons of MRN, and further reported that infusions of the GABA<sub>B</sub> agonist, baclofen, into MRN produced long-lasting theta. They concluded (Varga *et al.*, 2002) that the

effects of baclofen on theta ‘resulted from suppression of the serotonergic output from the median raphe’.

In examinations of the effects of manipulations of MRN on the hippocampal EEG in awake rabbits, Vinogradova and colleagues (Kitchigina *et al.*, 1999; Vinogradova *et al.*, 1999) showed that low-amplitude MRN stimulation disrupted the bursting discharge of medial septal cells and abolished theta in the hippocampus, and that the reversible suppression of MRN with local injections of lidocaine increased the frequency and regularity of discharge of theta-bursting neurons of the septum and hippocampus and produced continuous theta in the hippocampus. Kitchigina *et al.* (1999) concluded that ‘the median raphe nucleus can be regarded as a functional antagonist of the reticular formation, powerfully suppressing theta bursts of the medial septal area neurons and the hippocampal theta rhythm’. In a follow-up report, Kudina *et al.* (2004) demonstrated that single injections of the serotonin reuptake inhibitor, fluoxetine, into the lateral ventricles (intracerebroventricular) produced a greater than 50 percent reduction in the amplitude of theta that persisted for periods of 60–90 minutes.

### **Recent examination of the effects of MRN stimulation on the hippocampal EEG and hippocampal unit activity**

It has traditionally been thought that the hippocampal EEG consists of two states: large-amplitude irregular activity (LIA), and theta rhythm (Bland, 1986; Bland and Colom, 1993; Vertes and Kocsis, 1997). Although some early reports identified a third state of the hippocampal EEG, termed small irregular activity (SIA) (Vanderwolf, 1971; Whishaw, 1972), SIA has only recently received significant attention (Jarosiewicz *et al.*, 2002; Jarosiewicz and Skaggs, 2004a, 2004b). SIA appears to be much less prevalent than LIA and, according to recent reports (Jarosiewicz and Skaggs, 2004a, 2004b) is predominantly seen in transitions between stages of sleep, from sleep to waking, or during waking, with the presentation of novel or unexpected stimuli that are not accompanied by orienting movements. Jarosiewicz and Skaggs (2004b) have suggested that SIA represents a level of arousal intermediate between that of sleep and waking.

Early studies that examined the effects of MRN stimulation on the hippocampal EEG (Assaf and Miller, 1978; Yamamoto *et al.* 1979; Vertes, 1981) generally failed to define the specific properties of the EEG produced by such stimulation, commonly referring to it as hippocampal desynchronization, non-theta, or perhaps LIA. In contrast to this, Bland and colleagues (Jackson *et al.*, 2008) recently reported that MRN stimulation produced

small-amplitude irregular activity (SIA). For instance, they showed that high-amplitude ( $> 600\mu\text{A}$ ) stimulation of MRN gave rise to very low-amplitude ( $\sim 25\text{--}50\mu\text{V}$ ) EEG activity in the hippocampus, or, according to them, 'a near flattening of the electroencephalogram'. Jackson *et al.* (2008) stated that MRN stimulation 'does not elicit hippocampal field activity typical of the non-theta (LIA, sharp wave, slow oscillation) but rather produces an activated neocortex and small amplitude irregular hippocampal activity'. Their findings seemed to indicate, then, that the MRN is responsible for producing a third state of the hippocampal EEG (or SIA), during the unique conditions in which it is present in rats.

Although this remains a possibility, it may be the case that the very low-amplitude EEG (flattening) produced by MRN stimulation represents a nearly complete suppression of all hippocampal EEG activity (SIA, LIA and theta) rather than the generation of a third pattern of activity – or SIA. Even if this activity is not SIA, Jackson *et al.* (2008) nonetheless drew (needed) attention to the fact that MRN stimulation does not (as generally believed) give rise to LIA, but rather produces a marked overall reduction in the amplitude of the hippocampal EEG – or profound blockade of theta. Supporting this (blocking theta): (1) Jackson *et al.* (2008) showed that low- (as opposed to high-) amplitude MRN stimulation produced less of a reduction in EEG amplitude, and partially blocked theta but did not elicit LIA; (2) previous reports have similarly demonstrated that MRN stimulation virtually flattened the hippocampal EEG (Vertes, 1981); and (3) pharmacological suppression of MRN generates long trains of uninterrupted theta (Kinney *et al.*, 1994, 1995, 1996; Vertes *et al.*, 1994; Varga *et al.*, 2002).

Regarding possible mechanisms for the suppression of theta with MRN activation, Jackson *et al.* (2008) found that MRN stimulation significantly inhibited the activity of several types of cells of the hippocampus, including phasic theta-on, tonic theta-on, theta-off and non-theta related cells. Specifically, MRN stimulation completely inhibited the activity of 40 percent (16/40) of phasic theta-on cells, produced a marked decrease in firing with a loss of rhythmicity in 53 percent (21/40) of these cells, and no change in discharge rates but a loss of rhythmicity in 7 percent of the cells. In a somewhat similar manner, MRN stimulation produced: (1) a reduction in firing in 68 percent (13/19) of tonic theta-on cells; (2) an increase in discharge in 16 percent (3/19) of them; and (3) no change in activity in another 16 percent of cells. All six of the theta-off cells (those firing at higher rates during non-theta than during theta) showed reduced rates of discharge with MRN stimulation, generally delivered during non-theta conditions. The authors proposed that the latter finding (i.e., theta-off cell suppression) supports their

position that MRN stimulation produces a third state of the hippocampal EEG which is different from theta and LIA – that is, MRN stimulation suppresses the activity of theta-off cells during LIA, and it might be expected to enhance it, if MRN stimulation produced LIA (Jackson *et al.*, 2008).

In sum, Jackson *et al.* (2008) showed that MRN stimulation inhibited the activity of the large majority of both theta-on (phasic and tonic) and theta-off cells in the hippocampus, which undoubtedly contributes to the marked suppression (flattening) of theta/hippocampal EEG with MRN stimulation.

### **Unit activity in the median raphe nucleus in relation to the hippocampal EEG – serotonergic and non-serotonergic neurons**

In an initial examination of the discharge properties of DRN and MRN neurons in urethane anesthetized rats, we showed that a relatively large percentage of cells of both nuclei fired synchronously with the theta rhythm (Kocsis and Vertes, 1996). For instance, with respect to MRN, 5 of 10 MRN cells exhibited theta rhythmical patterns of discharge and high unit-theta coherence values (0.47 to 0.89), indicating strong theta rhythmicity. Interestingly, the 'theta-rhythmic' MRN cells fired at high mean rates of activity (21–42 Hz), suggesting that they were not serotonergic neurons – or the classically defined population of 5-HT raphe cells with slow (1- to 4-Hz), regular rates of discharge. Accordingly, it was tentatively suggested that these MRN cells were GABAergic neurons.

In a subsequent comprehensive analysis of the firing characteristics of MRN neurons with respect to theta in anesthetized rats, we demonstrated that 145/181 MRN cells (or  $\sim 80$  percent) showed theta-related changes in activity; that is, they fired at significantly higher (theta-on cells) or lower (theta-off cells) rates of activity during theta compared to non-theta states (Viana Di Prisco and Vertes, 2006). The theta-on (68 percent) and theta-off (32 percent) MRN neurons were further divided into slow- ( $\sim 1\text{--}3$  Hz), moderate- (5–11 Hz) and fast-firing ( $> 12$  Hz) cells. Unlike the previous report, which involved a much smaller sample of MRN neurons (Kocsis and Vertes, 1996), approximately one-third (49/145) of MRN cells discharged at slow regular rates of activity similar to 'classic' serotonin-containing neurons of the raphe and were presumed to be 5-HT cells (but see below). About 30 percent of the slow-firing (SF) neurons were theta-off cells, while the remaining (or the majority) were theta-on cells.

Figure 4 depicts discharge profiles of a slow-firing theta-off (Figure 4A, B) and SF theta-on (Figure 4C, D)

**Figure 4** (A) The discharge characteristics of a slow firing (SF) cell of the median raphe nucleus that decreased in discharge from non-theta (left side) to theta elicited with tail pinch (TP, horizontal gray bar). (B) Superimposed actions potentials of the theta-off cell (A) showing a wide spike ( $\sim 2$  ms) and interspike interval histogram (ISIH) demonstrating the slow rate of firing of the cell ( $\sim 1.2$  Hz) (0.8-s peak in ISIH) during non-theta conditions. (C) Superimposed actions potentials of the SF theta-on cell of (D) showing a wide spike ( $\sim 2$  ms) and the ISIH demonstrating enhanced firing of the cell to 2.4 Hz (0.4-s peak in ISIH) in the 10-s period following TP-elicited theta. (E) The discharge properties of the SF theta-on cell of C showing increased rates of firing during TP-elicited theta.

MRN neuron. As illustrated, both the SF theta-on and the theta-off cells had wide spikes ( $\sim 2$  ms) (Figure 4B, C) and fired at significantly decreased (theta-off) or increased (theta-on) rates of activity during tail pinch (TP) elicited theta (Figure 4A, D).

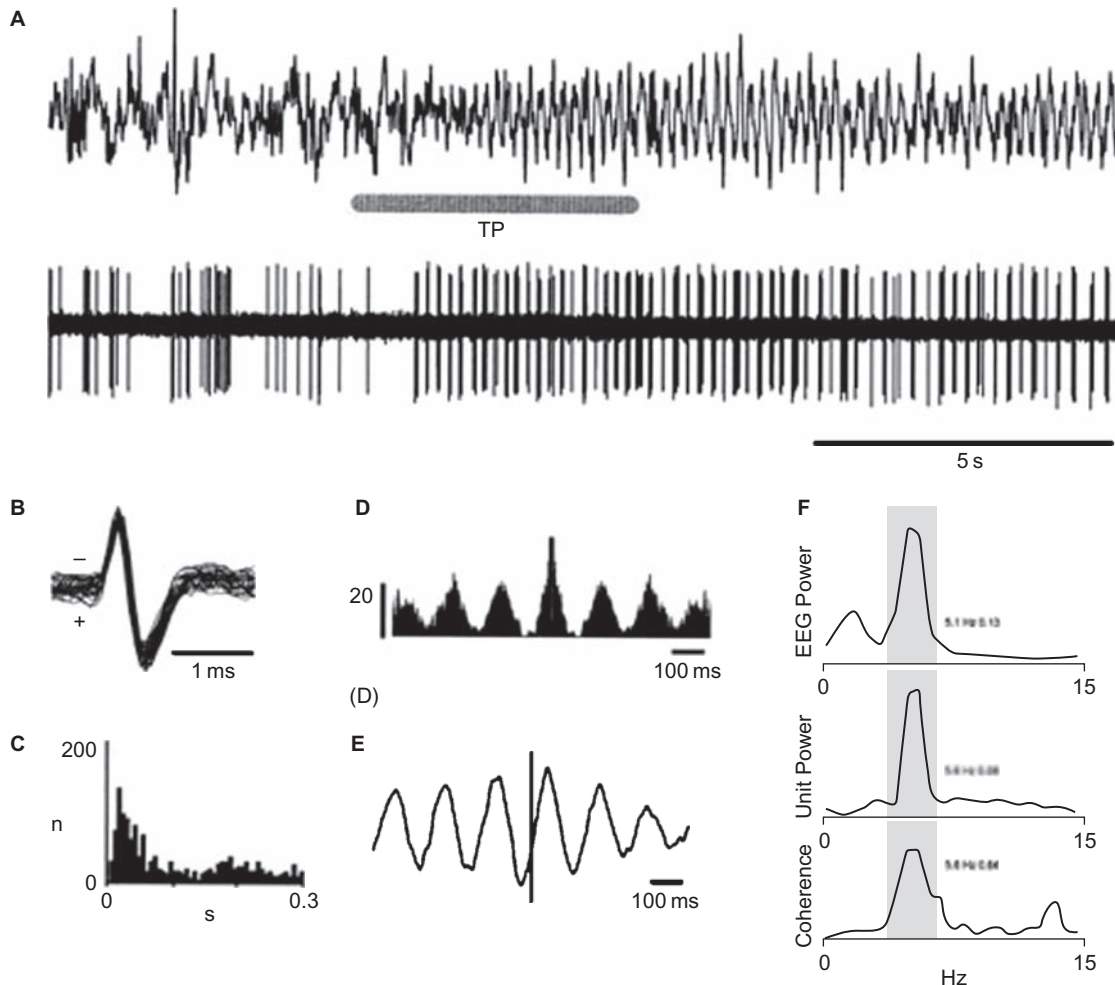

As will be discussed in greater detail below, several recent reports, using various methods to identify 5-HT raphe neurons (mainly of the DRN), have shown that serotonergic cells are not a homogeneous population of neurons as originally described (slow, regular rates of

discharge and wide action potentials) (Aghajanian *et al.*, 1978; Vandermaelen and Aghajanian, 1983; Jacobs and Fornal, 1991; Jacobs and Azmitia, 1992), but fire over a range of frequencies up to  $> 20$  Hz (Allers and Sharp, 2003; Kocsis *et al.*, 2006; Urbain *et al.*, 2006). In this regard, we identified a second population of MRN neurons, termed moderately-firing (MF) cells, that discharged at mean baseline rates (non-theta) of  $\sim 7$  Hz (range 5–11 Hz) (Viana Di Prisco *et al.*, 2002). These cells constituted about 37 percent (53/145) of MRN neurons and,

unlike SF neurons, more were theta-off (60 percent) than theta-on (40 percent) cells. The theta-off MF cells showed a dramatic decrease in firing rate from non-theta to theta from mean rates about 7.0 Hz to rates of 2.0 Hz. An interesting subset of theta-off MF cells discharge at very regular rates similar to classic slow-firing MRN neurons; the main difference between the two was rates of discharge during baseline conditions (SF cells  $\sim 1\text{--}3\text{ Hz}$  and MF cells  $\sim 5\text{--}7\text{ Hz}$ ). Although not systematically examined, a few regular-firing MF theta-off cells were strongly inhibited by systemic injections of the 5-HT<sub>1A</sub> agonist, 8-hydroxy-2-(di-*n*-propylamino)tetralin (8-OH-DPAT), indicating that they were serotonergic neurons.

Finally, a third population of MRN neurons (37/145) discharged at high baseline rates of activity (12–22 Hz) and exhibited further increases from non-theta to theta states. All fast-firing (FF) MRN neurons had narrow action potentials, were theta-on cells (no theta-off FF MRN neurons) and were subdivided into tonic and phasically discharging cells. The phasic FF MRN neurons not only showed pronounced increases in rates of discharge with theta (from mean rates of 12.0 to 20.7 Hz), but also fired rhythmically, synchronous with theta. Figure 5 depicts one such cell. As illustrated (Figure 5A), the cell fired arrhythmically in the absence of theta and rhythmically at increased rates with TP-elicited theta. The

**Figure 5** (A) The discharge characteristics of a fast-firing median raphe nucleus (MRN) cell that increased in rate of discharge and fired rhythmically to tail pinch (TP)-elicited theta. (B) Superimposed APs of the cell showing a narrow spike width of  $\sim 1\text{ ms}$ . (C) ISI histogram showing clustering at two intervals ( $\sim 20\text{ ms}$  and  $\sim 200\text{ ms}$ ) reflecting inter- and intra-burst frequencies during theta. (D, E) Autocorrelogram and crosscorrelogram depicting the rhythmic discharge of the cell (D) locked to theta (E) during theta conditions. (F) spectral and coherence plots showing peaks in the EEG and unit signals at theta frequency ( $\sim 5.6\text{ Hz}$ ) and significant coherence (0.64) between EEG and unit signals at theta frequency.

rhythmical discharge of the cell is shown by: (1) the second peak in the ISI histogram at approximately 200ms (5Hz) (Figure 5C); (2) rhythmical peaks at theta frequency in the autocorrelogram (Figure 5D); (3) unit-EEG locked oscillations in the cross-correlogram (Figure 5E); (4) peaks in the unit and EEG autospectra at approximately 5 Hz (Figure 5F); and (5) pronounced coherence between unit and EEG signals at theta frequency (Figure 5F). Rhythmic FF cells fired at higher rates and showed greater coherences with theta during TP-elicited than during spontaneous theta; that is, rates and coherences of 20.7 Hz and 0.67 with TP theta compared to 16.2 Hz and 0.56 with spontaneous theta.

The discharge characteristics of these neurons were very similar to those of the previously described subpopulation of cells that fired at high rates (20–40 Hz) phase-locked to theta (Kocsis and Vertes, 1996). Based on this property and others, including narrow APs, these cells were considered to be GABAergic neurons.

In this regard, in addition to 5-HT cells, the median raphe nucleus contains significant numbers of GABAergic neurons (Mugnaini and Oertel, 1985; Jacobs and Azmitia, 1992; Maloney *et al.*, 1999) which have been shown to contact and inhibit 5-HT MRN cells (Forchetti and Meek, 1981; Nishikawa and Scatton, 1985a, 1985b). As discussed, injections of GABA<sub>A</sub> (Kinney *et al.*, 1995) or GABA<sub>B</sub> agonists (Varga *et al.*, 2002) into MRN generate persistent theta. This suggests a GABAergic MRN influence on 5-HT cells of MRN in the modulation of the hippocampal EEG.

Supporting earlier findings, Li *et al.* (2005) recently showed, using reverse dialysis, that infusions of the GABA<sub>A</sub> agonist muscimol, or the GABA<sub>B</sub> agonist baclofen, into MRN generated prolonged theta, presumably through the inhibition of 5-HT cells of MRN, whereas infusions of the GABA<sub>A</sub> antagonist bicuculline into MRN eliminated theta, presumably through the disinhibition of 5-HT MRN cells.

Interestingly, however, bicuculline had complex effects that were partially attributed to the presence of GABA<sub>A</sub> receptors on both 5-HT cells and GABAergic interneurons of the MRN. Specifically, at low concentrations bicuculline either suppressed theta or gave rise to a short period of theta before desynchronizing the hippocampal EEG, while at high concentrations bicuculline produced a 5- to 10-minute period of desynchronization followed by long-lasting theta. Presumably, these effects largely reflect a delicate balance between sites of actions of bicuculline; that is, either a disinhibition of GABAergic interneurons resulting in stronger inhibitory actions on 5-HT MRN neurons and theta, or a direct disinhibition of 5-HT MRN cells and hippocampal EEG desynchronization.

Based on the foregoing, we suggested the following for various types of MRN cells (Viana Di Prisco *et al.*, 2002):

(1) the slow-firing cells (theta-on and theta-off) and a subset of the moderately discharging cells were serotonergic neurons, and the phasic and tonic fast-firing cells were mainly GABAergic neurons; (2) the 5-HT theta-off (or desynchronization-on) cells were projection neurons, and the 5-HT theta-on and GABAergic cells were primarily interneurons; and (3) these populations of cells mutually interact in the modulation of the hippocampal EEG. In effect, the activation of local 5-HT theta-on cells as well as the GABAergic theta-on cells would inhibit 5-HT theta-off projection cells to release or generate theta, whereas suppression of 5-HT theta-on and/or GABAergic theta-on activity would disinhibit 5-HT theta-off (desynchronization-on) cells, resulting in a blockade of theta or a desynchronization of the hippocampal EEG.

A recent examination (Kocsis *et al.*, 2006) of the discharge properties of MRN and DRN neurons, combined with procedures for transmitter identification (juxtacellular labeling), largely supports the foregoing scheme – with some additional complexity. Specifically, Kocsis *et al.* (2006) described the discharge properties of ten serotonergic and five non-serotonergic cells of the DRN/MRN. Of the ten 5-HT cells, the activity of four corresponded to classic 5-HT neurons – i.e., broad spikes and, as indicated by the authors, ‘a slow metronome-like firing mode’. Three of four of the slow firing neurons were theta-off cells and the other one was a theta-on cell. Interestingly, three of the ten serotonergic neurons fired at high rates of activity (> 8 Hz) during theta and non-theta states, and synchronously (phase-locked) to hippocampal theta. The discharge characteristics of these cells were very similar to subsets of fast-firing cells described previously (Kocsis and Vertes, 1996; Viana Di Prisco *et al.*, 2002), which were tentatively identified as GABAergic neurons. Additional studies using larger samples of cells (with transmitter identification) will be needed to determine the relative proportion of FF ‘theta rhythmic’ cells of DRN/MRN that are GABAergic or serotonergic neurons. If it proves to be the case that a significant percentage of these cells are serotonergic, it would not alter the foregoing model for MRN involvement in the hippocampal EEG. Specifically, the fast-firing ‘theta rhythmic’ 5-HT MRN neurons could serve a role similar to that proposed for the slow- and moderately-firing 5-HT theta-on cells – i.e., 5-HT interneurons that modulate the activity of 5-HT MRN projection cells in the control of the hippocampal EEG. This was also indicated by Kocsis *et al.* (2006), who stated that ‘Rhythmically firing serotonergic neurons have local axon collaterals and can therefore participate in suppressing the activity of slow firing neurons either through 5-HT<sub>1A</sub> autoreceptors or through a local 5-HT<sub>2</sub> receptor-activated GABAergic circuit.’

In one of the few studies examining the activity of MRN cells in behaving animals, Jacobs and colleagues

(Marrosu *et al.*, 1996) showed in awake cats that putative 5-HT cells of MRN exhibited properties indicative of a role in the desynchronization of the hippocampal EEG. These cells fire at highest rates during 'automatic' behaviors of waking and slow-wave sleep (SWS) (desynchronized states of the hippocampus), and at lowest rates during the exploration of waking and REM sleep (theta states) (Jacobs and Azmitia, 1992; Marrosu *et al.*, 1996).

#### **Site(s) of action of MRN desynchronizing effects on the hippocampal EEG**

It is now well established that hippocampal theta is generated by a network of structures extending from the brainstem to the hippocampus (Bland and Colom, 1993; Kocsis and Vertes, 1994; Vertes and Kocsis, 1997; Vertes *et al.*, 2004). Specifically, during theta, tonically firing cells of nucleus pontis oralis (RPO) of the rostral pons activate putative glutamatergic neurons of the supramammillary nucleus (SUM) of the hypothalamus, which convert this steady barrage into a rhythmical pattern of discharge which is relayed to 'pacemaking' cells of the medial septum and then to the hippocampus (HF) to generate theta. Accordingly, MRN could modulate the hippocampal EEG via actions on one or more structures of the theta-generating system; that is, RPO, SUM, the medial septum/diagonal band nuclei (MS/DBv) or the hippocampus. As described, MRN distributes significantly to each of these sites: RPO, SUM, MS/DBv and HF (Vertes and Martin, 1988; Morin and Meyer-Bernstein, 1999; Vertes *et al.*, 1999).

It has been shown that MS/DBv lesions completely abolish theta (Vertes and Kocsis, 1997; Vertes *et al.*, 2004); this suggests that the medial septum is critical for the control of the hippocampal EEG – theta and non-theta. Accordingly, the desynchronizing actions of MRN on the hippocampal EEG would appear to be primarily mediated through the MS/DBv. In this regard, MRN stimulation disrupts the rhythmical discharge of septal pacemaking cells and abolishes theta (Assaf and Miller, 1978; Kitchigina *et al.*, 1999), while the suppression of MRN in awake rabbits (with injections of lidocaine) was found to increase the frequency and regularity of discharge of septal bursting neurons and produce continuous theta in the hippocampus. In addition, Kinney *et al.* (1996) showed that injections of the 5-HT<sub>1A</sub> agonist, 8-OH-DPAT, into MRN (which inhibits 5-HT MRN neurons) rhythmically activated septal pacemaking cells and generated theta.

As discussed, Bland and colleagues (Jackson *et al.*, 2008) recently demonstrated that high-frequency MRN stimulation both desynchronized the hippocampal EEG and inhibited the activity of a large percentage of phasic

and tonic theta-on cells of the hippocampus. While the authors acknowledge that it is difficult to determine whether MRN-elicited effects are routed through the septum and directly affect the hippocampus, their findings favor a direct action on the hippocampus. It is unclear, however, whether the suppressive effects of MRN stimulation on unit activity in the hippocampus indirectly resulted from the disruption of bursting activity of MS/DBv neurons – which, as discussed above, occurs with MRN stimulation.

In summary, the MS/DBv is the nodal point for converting ascending influences into patterns of hippocampal EEG activity, and as such the activation or disruption of a common pool of MS/DBv cells would appear responsible for controlling theta and non-theta states, respectively, of the hippocampal EEG.

#### **Functional significance of theta and by inference the functional role of MRN-elicited blockade of theta- or the desynchronization (non-theta) of the hippocampal EEG**

Although the theta rhythm has been implicated in several functions including 'arousal' (Green and Arduini, 1954) and, recently, sensorimotor integration (Bland and Colom, 1993; Bland and Oddie, 2001), the prevailing view is that theta serves a critical role in mnemonic processes of the hippocampus (Vertes and Kocsis, 1997; Buzsáki, 2002; Kirk and Mackay, 2003; Vertes *et al.*, 2004; Hasselmo, 2005; Vertes, 2005). Several lines of evidence indicate a direct involvement of theta in memory. This includes the demonstration that: (1) discrete MS/DBv lesions that abolish theta produce severe learning/memory deficits in rats; (2) LTP is optimally elicited in the hippocampus with stimulation at theta frequency (i.e., theta burst or primed burst potentiation); (3) stimulation delivered in the presence of theta, and on its positive phase, significantly potentiates population responses in the hippocampus; (4) the loss of LTP with primed burst (theta) stimulation in mutant mice is accompanied by a pronounced disruption of place cell activity and spatial memory; and (5) theta is present in humans during the encoding and retrieval stages of various tasks (for review, see Vertes *et al.*, 2004).

We recently advanced the theory that theta serves as a 'tag' for short-term memory in the hippocampus (Vertes, 2005). In short, we proposed that the hippocampus receives two main types of input; theta from ascending brainstem-diencephalo-septal systems, and 'information bearing' mainly from thalamocortical and cortical systems. The temporal convergence of activity of these two systems results in the encoding of information in the hippocampus, primarily reaching it via cortical routes. By analogy

to processes associated with long-term potentiation (LTP), we suggest that theta represents a strong depolarizing influence on NMDA receptor-containing cells of the hippocampus. The temporal coupling of a theta-induced depolarization and the release of glutamate to these cells from intra- and extra-hippocampal sources activates them. This, in turn, initiates processes leading to a (short-term) strengthening of connections between presynaptic ('information-bearing') and postsynaptic neurons of the hippocampus. Theta is selectively present in the rat during active exploratory movements. During exploration, a rat continually gathers and updates information about its environment. If this information is temporally coupled to theta (as with the case of locomotion), it becomes temporarily stored in the hippocampus by mechanisms similar to the early phase of LTP (E-LTP). If the exploratory behavior of the rat goes unreinforced, these relatively short lasting traces (1–3 hours) gradually weaken and eventually fade, to be reupdated. On the other hand, if the explorations of the rat lead to rewards (or punishments), additional modulatory inputs to the hippocampus become activated and convert short-term, theta-dependent memories into long-term stores.

If, as indicated, theta serves a critical role in memory, the question arises regarding the functional significance of the serotonergic MRN system that actively blocks theta. A likely possibility may be that the 5-HT MRN system suppresses or suspends memory. In this regard, several reports have shown that serotonergic agents block LTP and that 5-HT antagonists (mainly 5-HT<sub>3</sub> antagonists) enhance LTP and/or memory (Corradetti *et al.*, 1992; Staubli and Otaky, 1994; Staubli and Xu, 1995; Buhot, 1997). MRN may be an important part of a system of connections that directs the hippocampus to essentially disregard insignificant environmental events. In a variant of this, Kitchigina *et al.* (1999) suggested that the MRN may serve to terminate attention or shift attention to new stimuli, thereby stabilizing previously learned information.

In addition to its effects on the hippocampal EEG, the MRN serves a well-documented role in the control of locomotion. MRN stimulation suppresses locomotor behavior (Graeff *et al.*, 1980; Peck and Vanderwolf, 1991), while various manipulations that inhibit the activity of MRN cells produce locomotion (Paris and Lorens, 1987; Hillegaart and Hjorth, 1989; Wirtshafter *et al.*, 1993; Shim *et al.*, 1997). Further, Sinnamon *et al.* (2000) demonstrated that injections of GABA (and agonists) into MRN enhanced hypothalamic-induced stepping behavior (locomotion) and increased the power of theta in the 4- to 5-Hz band. The possible dual MRN control of locomotion and states of the hippocampal EEG may have important functional consequences. It is obviously critical for a rat (or other species) when exploring its environment to

commit relevant aspects of it to memory, hence the coupling of locomotion with theta to encode information during exploratory behaviors. On the other hand, there may be less of a demand to commit information to memory when an animal is stationary or engaged in automatic behaviors such as grooming or consumatory acts (non-theta states); hence the absence of theta during these conditions.

### **Unit activity in the dorsal raphe nucleus (DRN) in relation to the hippocampal EEG (serotonergic and non-serotonergic neurons) and possible functional roles**

In an early examination of the discharge properties of DRN neurons in the behaving rat, we (Kocsis and Vertes, 1992) showed that activity of 17 of 30 DRN cells was correlated with the hippocampal theta rhythm; the remaining 13 cells showed no relationship to theta. It was generally the case that theta-related cells fired irregularly during quiet waking and slow wave sleep (non-theta states), and changed to a regular bursting pattern synchronous with theta during waking with movements and REM sleep. Units were divided into slow-firing, fast-firing (11–40 Hz) and very fast-firing (55–70 Hz) cells, and subpopulations of each fired rhythmically with theta. In a follow-up report in the urethane anesthetized rat (Kocsis and Vertes, 1996), a slightly higher percentage of DRN neurons (7/10) was correlated with theta and discharge rates varied over a wide range (5–42 Hz) to include slow- and fast-firing DRN neurons.

As discussed with MRN, it was thought that the slow-firing neurons of these reports (Kocsis and Vertes, 1992, 1996) were serotonergic cells and the fast-firing neurons were non-5-HT or mainly GABAergic cells. While this division may still largely hold, several recent reports have indicated that slow-firing DRN cells are not exclusively serotonergic and subsets of fast-discharging DRN units are 5-HT neurons. For instance, partially consistent with classic descriptions, Allers and Sharp (2003), using juxtacellular techniques, reported that 8 of 10 DRN cells with narrow spikes and high discharge rates (>12 Hz) were GABAergic neurons. With respect, however, to slow- and regular-firing cells with broad spikes, about half (12/24) were monoaminergic neurons (serotonin or dopamine), but the other half were not – indicating that some neurons with these characteristics are not serotonergic cells. In like manner, Kocsis *et al.* (2006) recently demonstrated that 7 of 10 slow-firing neurons of DRN/MRN were 5-HT cells, while the remaining three fired at high baseline rates (>8 Hz) phase-coupled to theta. Of the five non-serotonergic cells, 2/5 discharged at low rates (similar

to the majority of 5-HT cells); while 3/5 fired at high rates (~10 Hz), particularly in the presence of theta. The activity of one of these cells was phase-coupled to theta. The foregoing indicates, then, that most DRN cells exhibit classic characteristics; that is, slow-firing cells with broad APs are 5-HT neurons and fast-firing cells with narrow spikes are non-5-HT or mainly GABAergic neurons. Despite this, it seems that relatively significant numbers of DRN neurons may not fit these categories.

With regard to a DRN influence on the hippocampal EEG (theta or non-theta), it appears unlikely that DRN has a direct role in the generation of theta or desynchronized states of the hippocampal EEG – as demonstrated for the MRN. For instance, electrical stimulation of the DRN has no effect on the hippocampal EEG (Vertes, 1981). The DRN receives descending theta-related input from forebrain structures such as the supramammillary nucleus (Vertes, 1992), which may rhythmically drive DRN neurons at theta frequencies (Kocsis and Vertes, 1992, 1996; Kocsis *et al.*, 2006). The theta rhythmic cells of DRN could, in turn, exert effects on the MRN in the modulation of the hippocampal EEG, in the manner in which local 5-HT and GABAergic interneurons of the MRN modulate 5-HT MRN projection cells in the blockade of theta or the desynchronization of the hippocampal EEG. The DRN projects to (Vertes, 1991; Vertes and Kocsis, 1994; Morin and Meyer-Bernstein, 1999; Tischler and Morin, 2003) and functionally affects the MRN (Mokler *et al.*, 2009). In addition, through its widespread forebrain projections (Vertes, 1991; Morin and Meyer-Bernstein, 1999; Waselus *et al.*, 2006; Kanno *et al.*, 2008) the DRN may provide theta synchronous input to several forebrain structures known to exhibit theta rhythmicity, which include the anterior thalamus, amygdala, striatum and prefrontal cortex (Vertes *et al.*, 2001; Albo *et al.*, 2003; Pape *et al.*, 2005; DeCoteau *et al.*, 2007; Mitchell *et al.*, 2008; Young and McNaughton, 2009). The DRN may serve a critical role in coordinating the activity of these various structures during theta states or behaviors, possibly to bind emotional and sensorimotor aspects of behavior.

<sup>2</sup>*Departments of Neurology and Cellular & Molecular Physiology, Yale University School of Medicine, and Veterans Affairs Medical Center, New Haven, Connecticut*

**Abstract:** Many neurons within the medullary raphe project to nuclei that control respiratory motor output. Through release of serotonin (5-HT) and the co-localized neuropeptides substance P and thyrotropin-releasing hormone, these neurons provide an essential tonic drive that maintains ventilation. Many 5-HT neurons are closely associated with large arteries of the brainstem, where they respond to changes in arterial CO<sub>2</sub> levels by increasing their firing rate. These properties allow them to play an important role as central respiratory chemoreceptors, causing an increase in ventilation in response to increased CO<sub>2</sub> levels and returning CO<sub>2</sub> and pH back to normal. Some 5-HT neurons in the midbrain may play a similar role in sensing changes in blood CO<sub>2</sub>, and may induce arousal when CO<sub>2</sub> levels increase during sleep. Defects in 5-HT neurons occur in a variety of human diseases and may contribute to abnormalities of respiratory control and blood gas homeostasis.

## Introduction

The neural control of breathing and its role in human disease has been the subject of intensive research. Much of this effort has been aimed at identifying neurons that act as central respiratory chemoreceptors (CRCs) – neurons that sense changes in CO<sub>2</sub> and initiate ventilatory changes that help maintain pH homeostasis. In this chapter, we discuss evidence that 5-HT neurons are CRCs. We review their role in the control of breathing and the ventilatory response to hypercapnia, and discuss data showing they have intrinsic chemosensitivity. We also review data from mice in which 5-HT neurons are genetically deleted, and in which there is a large decrease in the response to increased CO<sub>2</sub>. Finally, we discuss the implications for human disease.

## The 5-HT system stimulates respiratory output

Substantial evidence obtained from *in vitro* and *in vivo* work indicates that 5-HT neurons in the medullary raphe cause an increase in respiratory output via a neuromodulatory effect on brainstem neurons (Richerson, 2004; Hodges and Richerson, 2008a). Their ability to influence breathing is based in part on their extensive connections to multiple elements of the respiratory control network throughout the brainstem, including the pre-Bötzinger Complex (pre-BötC),

nucleus tractus solitarius (NTS), retrotrapezoid nucleus, and phrenic and hypoglossal motor nuclei.

Many studies have examined the influence of the 5-HT system on respiratory output *in vitro* and *in vivo*. For example, an excitatory effect of 5-HT receptor activation has been shown using *in vitro* slice preparations containing the pre-BötC, a region of the medulla that is involved in respiratory rhythm generation (Smith *et al.*, 1991). Blockade of 5-HT<sub>2A</sub> receptors leads to disruption of rhythm generation in slices containing the pre-BötC (Pena and Ramirez, 2002; Ptak *et al.*, 2009). In addition, the neuropeptides substance P (SP) and thyrotropin-releasing hormone (TRH), which are both co-localized in 5-HT neurons of the medulla, have strong stimulatory effects on respiratory activity in slices (Dekin *et al.*, 1985; Funk *et al.*, 1994; Greer *et al.*, 1996; Pena and Ramirez, 2004). The effects of 5-HT, TRH and SP occur in part due to depolarization of motor neurons (Bayliss *et al.*, 1997; Reklung *et al.*, 2000) and other respiratory neurons (Reklung *et al.*, 1996; Pena and Ramirez, 2004). In addition, TRH induces bursting pacemaker activity in the NTS (Dekin *et al.*, 1985), and 5-HT has the same effect on respiratory neurons in the pre-BötC (Ptak *et al.*, 2009). This increased bursting would enhance respiratory output. 5-HT, TRH and SP also each stimulate respiratory output in the *en bloc* brainstem-spinal cord preparation of the newborn rat (Morin *et al.*, 1990; Ptak and Hilaire, 1999; Richerson, 2004). Similarly, there is a large body of data demonstrating that raphe neurons, as well as exogenous 5-HT and TRH receptor agonists, stimulate

breathing *in vivo* (Richerson, 2004). For example, direct electrical stimulation of neurons in the medullary raphe in anesthetized, paralyzed and ventilated cats *in vivo* leads to an increase in respiratory frequency and phrenic nerve activity (Holtman *et al.*, 1986).

Although there is evidence that 5-HT, TRH, and SP each have a predominantly stimulatory effect on breathing *in vivo* (Manzke *et al.*, 2003; Richerson, 2004; Hodges and Richerson, 2008a; Hodges *et al.*, 2008), there are also contradictory data. For example, some older studies have concluded that 5-HT neurons have an inhibitory effect on respiration *in vivo* (Olson *et al.*, 1979; Lalley *et al.*, 1997). However, there are reasons to believe that the data that led to this conclusion are subject to other interpretations (Richerson, 2004; Hodges and Richerson, 2008a), and the bulk of the data support the conclusion that 5-HT neurons provide a tonic excitatory drive to the respiratory network *in vivo*. Since 5-HT neurons are tonically active during wakefulness, their effect on breathing would be expected to be greatest during the awake state. Thus, a reduction in firing of 5-HT neurons during sleep (Jacobs *et al.*, 1990, 2002; Fenik *et al.*, 2005) may contribute to the decrease in ventilation that occurs during sleep.

### The 5-HT system is involved in the response to hypercapnia

There are relatively few conditions other than changes in the state of arousal that alter the firing of 5-HT neurons

*in vivo* (Jacobs and Azmitia, 1992; Jacobs and Fornal, 1999). One is a change in the level of inspired CO<sub>2</sub>. In unanesthetized behaving cats, a subset of physiologically-identified 5-HT neurons in the raphe obscurus and in the dorsal raphe respond to hypercapnia with an increase in firing rate (Veasey *et al.*, 1995, 1997). Interestingly, some of these neurons respond to CO<sub>2</sub> less during sleep (Veasey *et al.*, 1995), consistent with the observation that there is a reduction in the ventilatory response to CO<sub>2</sub> during sleep. These data are supported by other *in vivo* experiments in unanesthetized animals showing that hypercapnia activates c-fos in neurons of the medullary raphe, in some cases defined as serotonergic (see Figure 2A, below) (Larnicol *et al.*, 1994; Haxhiu *et al.*, 2001; Okada *et al.*, 2002; Pete *et al.*, 2002; Johnson *et al.*, 2005). The conclusion that 5-HT neurons are chemosensitive *in vivo* is also supported by experiments using microdialysis in the hypoglossal nucleus of unanesthetized mice, which showed that hypercapnia (mean inhaled CO<sub>2</sub> = 7%) causes a 2.5-fold increase in extracellular 5-HT levels (Kanamaru and Homma, 2007). The response to hypercapnia of 5-HT neurons in the ventrolateral medulla is much smaller in halothane anesthetized rats (Mulkey *et al.*, 2004), probably due to a depressant effect of halothane on respiratory chemoreception.

*In vivo* experiments have shown that microinjection of acetazolamide into the medullary raphe, which causes focal acidosis, stimulates respiratory output (Bernard *et al.*, 1996). Similarly, focal CO<sub>2</sub> microdialysis in the

**Figure 1** 5-HT neurons increase their firing rate *in vitro* in response to an increase in CO<sub>2</sub> or decrease in pH. (A) Membrane potential ( $V_m$ ) of a medullary raphe neuron in culture under baseline conditions and when exposed to hypercapnia. (B) The firing rate of 5-HT neurons *in vitro* increases significantly in response to a small decrease in pH. Shown is the firing rate of a cultured midbrain raphe neuron (upper panel) in response to repeated changes in pH from 7.4 to 7.2 (lower panel). (A) Reproduced with permission from Wiley-Blackwell: *Journal of Physiology* (Wang *et al.*, 2002) 540:951–70, ©2002. medullary raphe of the rat increases ventilation in sleep, but not in the awake state (Nattie and Li, 2001). In contrast, the same approach does increase ventilation in awake goats (Hodges *et al.*, 2004a, 2004b).

### 5-HT neurons have cellular properties consistent with a role as CRCs

A subset of neurons from the ventromedial medulla increase their firing rate in brain slices and primary tissue culture when extracellular CO<sub>2</sub> is increased from 5 percent to 9 percent (Figure 1) (Richerson, 1995; Wang *et al.*, 1998). These neurons are stimulated to the same degree by a similar drop in pH at constant PCO<sub>2</sub> (isocapnic acidosis), indicating that the primary stimulus is pH and not CO<sub>2</sub> *per se*. These neurons respond maximally to changes in pH between 7.2 and 7.6, which is relatively close to the range of pH changes that occur under normal physiological conditions.

Neurons from the ventromedial medulla that are stimulated by acidosis have electrophysiological properties characteristic of 5-HT neurons, with a highly regular firing rate, a wide action potential and a prominent afterhyperpolarization (Jacobs and Azmitia, 1992; Mason, 1997; Wang *et al.*, 1998). Studies in both brain slices and culture using immunohistochemistry for tryptophan hydroxylase have shown that these acidosis-stimulated neurons are serotonergic (Wang *et al.*, 2001; Bradley *et al.*, 2002).

Chemosensitive 5-HT neurons in tissue culture and in brain slices continue to respond to hypercapnia after blockade of fast synaptic transmission either by antagonists of glutamate and GABA receptors or by high calcium/low magnesium solution (Richerson, 1995; Wang *et al.*, 2001; Bradley *et al.*, 2002). This does not prove that their ability to sense CO<sub>2</sub> is an intrinsic property, but that has recently been verified using acute dissociation, after which medullary 5-HT neurons from mice continue to be robustly chemosensitive (Wu *et al.*, 2008).

When mature, 5-HT neurons increase their firing rate to an average of 300 percent of their baseline level in response to a decrease in pH from 7.4 to 7.2 (Wang *et al.*, 1998, 2001, 2002). This is a large response compared to neurons studied in other proposed sites of CRCs (Putnam *et al.*, 2004). Interestingly, the response of 5HT neurons is not fully mature until several weeks after birth. In rat brain slices, there are few 5-HT raphe neurons that are chemosensitive until animals are older than postnatal day 12 (Wang and Richerson, 1999). In cell culture of rat and mouse raphe neurons there is a similar developmental time course (Wang and Richerson, 1999; Wu *et al.*, 2008), taking 10–11 days for 5-HT neurons to develop chemosensitivity. After that time the size of the response increases progressively until 4 weeks of age. This developmental maturation of chemosensitivity parallels development of the hypercapnic ventilatory response (HCVR) in rats *in vivo*. Several studies have shown that the HCVR of rats is not mature at birth, and undergoes postnatal

**Figure 2** 5-HT neurons are chemosensitive *in vivo* and are closely associated with large blood vessels. (A) A subset of neurons in the raphe pallidus express c-Fos when exposed to hypercapnia (right panel). Some of these neurons are immunoreactive for 5-HT (left panel). Open arrow: 5-HT neuron that does not express c-Fos. Closed arrows: 5-HT neuron that is immunoreactive for c-Fos. Asterisk: C-Fos positive neuron that does not express 5-HT. Scale bar: 20  $\mu$ m. (B) Medullary raphe neurons are closely related to the basilar artery and its large penetrating branches. Shown is a transverse section of the medulla. 5-HT neurons are immunostained with an antibody against tryptophan hydroxylase (green). Blood vessels are filled with fluorescent albumin (red). Scale bar: 200  $\mu$ m. (C). Shown is a neuron in the medullary raphe that was filled with biocytin (green) after patch-clamp recording. This neuron was stimulated by acidosis and was immunoreactive for tryptophan hydroxylase (blue). It had processes that were closely associated with large blood vessels (red). maturation after approximately P12 (Serra *et al.*, 2001; Stunden *et al.*, 2001; Davis *et al.*, 2006). It is possible that the developmental increase in chemosensitivity of 5-HT neurons is responsible in part for the developmental increase in the HCVR of rats.

5-HT neurons in both the medullary and midbrain raphe have an anatomical relationship with large penetrating arteries of the brainstem that is consistent with their playing a role in sensing blood CO<sub>2</sub> (Bradley *et al.*, 2002; Severson *et al.*, 2003). The highest concentration of 5-HT neurons in the medulla is immediately adjacent to the basilar artery and its large midline branches. Neurons in brain slices with this anatomical arrangement are stimulated by acidosis, and electron microscopic images show that processes of serotonergic neurons are located directly adjacent to the vessel walls (Figure 2B, C) (Bradley *et al.*, 2002; Severson *et al.*, 2003). The medullary raphe is traversed primarily by large arteries and is relatively devoid of veins, which would lead to a local tissue PCO<sub>2</sub> that more accurately reflects the PCO<sub>2</sub> of arterial blood rather than mixed venous blood. The fact that brainstem 5-HT neurons are closely related to blood vessels has also been shown for neurons in the nucleus raphe pontis and in the nucleus linealis rostralis which enwrap large penetrating arteries with their processes (Scheibel *et al.*, 1975). This anatomical specialization of 5-HT neurons would allow them to closely monitor blood CO<sub>2</sub> levels in a manner analogous to the way peripheral chemoreceptors monitor CO<sub>2</sub> in the carotid arteries and aorta. The level of PCO<sub>2</sub> in these large arteries more accurately parallels changes in lung ventilation than PCO<sub>2</sub> in more distal vessels such as capillaries.

### **Respiratory output and chemoreception are altered by interfering with the 5-HT system**

Supporting the hypothesis that 5-HT neurons are important for the ventilatory response to hypercapnia, disrupting the function of the medullary raphe system has an inhibitory effect on respiratory chemoreception. Reversible silencing with lidocaine or permanent lesions with ibotenic acid of the piglet medullary raphe both lead to a decrease in phrenic and hypoglossal nerve activity and the response to hypercapnia (Dreshaj *et al.*, 1998). After selective lesions of medullary 5-HT neurons with the toxin saporin conjugated to an antibody to the 5-HT transporter, there is a decrease in the ventilatory response to hypercapnia in both the awake state and non-REM sleep (Nattie *et al.*, 2004). Similarly, intraventricular injection of 5,7-dihydroxytryptamine lesions 5-HT neurons and causes hypoventilation (Olson *et al.*, 1979; Mueller *et al.*, 1984). Microdialysis of the medullary

raphe with 8-hydroxy-2-di-n-propylaminotetralin (8-OH-DPAT) to cause inhibition of 5-HT neurons via 5-HT<sub>1A</sub> autoreceptors also significantly decreases the ventilatory response to hypercapnia in piglets (Messier *et al.*, 2004). Thus, there are data from a variety of approaches that implicate 5-HT neurons as important CRCs *in vivo*.

To better evaluate the role of 5-HT neurons in control of breathing, new genetic approaches have been developed. These mouse models have taken advantage of knowledge about the transcription factors that are required for development of 5-HT neurons. The transcription factor Pet1 is found exclusively in 5-HT neurons (Hendricks *et al.*, 1999). In Pet-1 knockout (KO) mice, the number of 5-HT neurons is decreased by approximately 70 percent, with a concomitant decrease in 5-HT levels to 10–15 percent compared to wild-type animals (Hendricks *et al.*, 2003). Plethysmographic studies in these mice show a decrease in breathing frequency by about 30 percent at postnatal day 4.5 (Erickson *et al.*, 2007). At this time, there is also increased variability in the breathing pattern. This variability decreases with maturation of Pet-1 KO mice, with improved breathing at P 9.5, indicating a crucial role of 5-HT in the early maturation of respiration. At P4.5, Pet-1 KO mice respond normally to hypercapnic challenges with 5 percent CO<sub>2</sub>, raising the possibility that either 5-HT neurons do not play an important role as chemoreceptors until they are older and develop chemosensitivity (see above), or that the remaining 30 percent of 5-HT neurons were able to compensate for this loss (Blair, 2008). As adults, there is a decrease in the hypercapnic ventilatory response in male Pet-1 KO mice, but not in females (Hodges *et al.*, 2005), pointing to an important effect of gender in the ability to compensate for the decrease in 5-HT neurons.

Lmx1b is a homeobox gene that is crucial for the development of the brainstem 5-HT system, but is also involved in development of other neuronal types (Ding *et al.*, 2003). Lmx1b KO mice lack all 5-HT neurons, but also lack numerous other cell types and do not survive the perinatal period (Zhao *et al.*, 2006). Therefore, an alternative method has been developed. For this purpose, loxP sites were inserted around exons 4, 5, and 6 of the Lmx1b gene (Zhao *et al.*, 2006). These floxed *Lmx1b* mice were bred with mice that expressed Cre recombinase downstream of the enhancer region for Pet-1 (Scott *et al.*, 2005) to generate progeny in which Lmx1b is specifically deleted only in precursors of 5-HT neurons. These *Lmx1b<sup>fl/p</sup>* mice are born essentially devoid of any central 5-HT neurons (Zhao *et al.*, 2006).

Respiratory frequency is abnormally low in adult *Lmx1b<sup>fl/p</sup>* mice under resting conditions (Figure 3A), but ventilation is normal (Hodges *et al.*, 2008). Thus, it is possible for nearly normal baseline breathing to occur

in adults if 5-HT neurons are absent from embryonic life. However, baseline ventilation and the respiratory pattern are severely disrupted in *Lmx1b<sup>f/f/p</sup>* mice during the neonatal period, with an average of seven apneas per minute. This normalizes during the first 2 weeks of life (Richerson *et al.*, 2008). Interpretation of these results is complicated by the plasticity of the neonatal brain. The presence of near-normal breathing in adult *Lmx1b<sup>f/f/p</sup>* mice does not rule out a critical role of 5-HT neurons for normal respiratory output in adults. The respiratory network may simply be able to compensate for the absence of 5-HT neurons by undergoing a process of homeostatic plasticity during development (Turrigiano and Nelson, 2004). Future work will be required to determine the effect on breathing of acute deletion of all 5-HT neurons in adult animals.

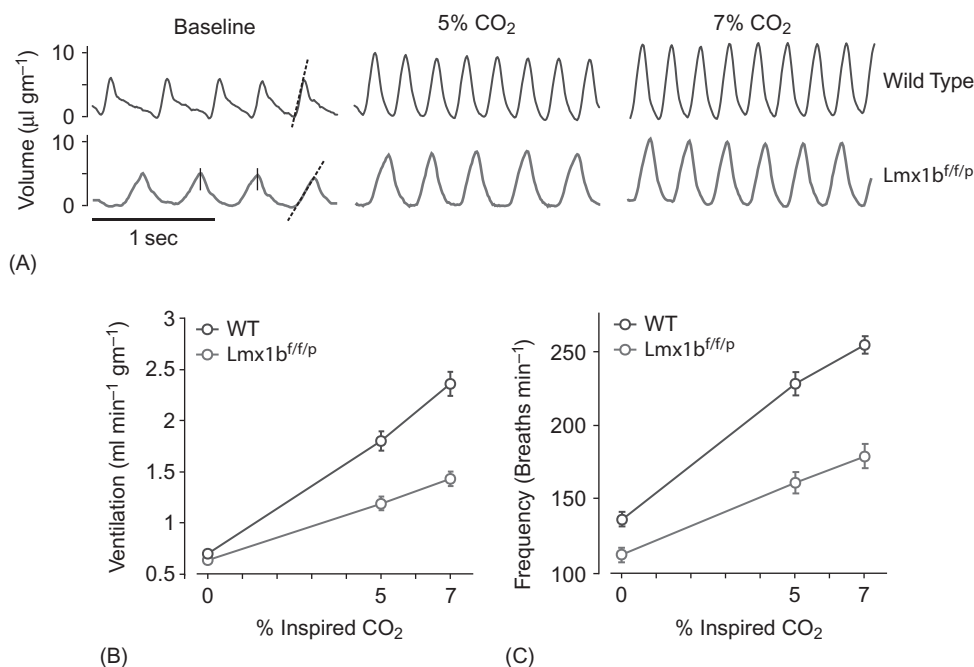

The response to hypoxia is normal in adult *Lmx1b<sup>f/f/p</sup>* mice. However, the ventilatory response to 5 percent and 7 percent CO<sub>2</sub> is reduced by about 50 percent (Figure 3B) (Hodges *et al.*, 2008). When *Lmx1b<sup>f/f/p</sup>* mice are exposed to 10 percent CO<sub>2</sub>, their HCVR is comparable to wild-type mice (Hodges and Richerson, 2008b), suggesting that 5-HT neurons are critical for the response to small changes in CO<sub>2</sub>, but the response to very high levels of CO<sub>2</sub> may

be mediated by non-5-HT neurons (Nattie, 1999). This is consistent with *in vitro* results demonstrating that 5-HT neurons have a large response to small changes in CO<sub>2</sub>/pH, whereas other CRC candidates are less sensitive (Putnam *et al.*, 2004).

*Lmx1b<sup>f/f/p</sup>* mice also have decreased ability to maintain core body temperature when exposed to cold. This failure in thermoregulation is due to a decrease in shivering and a decrease in metabolism of brown adipose tissue. It is unclear how this defect in thermoregulation relates to the defect in chemoreception, but it is possible that they are linked by metabolic rate, which is influenced by body temperature and influences blood gases. 5-HT neurons would be well situated to play a role in coordinating these functions.

### Role of 5-HT neurons in forebrain effects of hypercapnia

There is no evidence that 5-HT neurons in the midbrain raphe play a major role in control of breathing, and yet they are also chemosensitive to CO<sub>2</sub> *in vivo* (Veasey *et al.*, 1997)

**Figure 3** Mice with genetic deletion of 5-HT neurons have a defect in central respiratory chemoreception. (A) Plethysmograph recordings from WT (blue) and *Lmx1b<sup>f/f/p</sup>* (red) mice. *Lmx1b<sup>f/f/p</sup>* breathe with a slower frequency at baseline, and do not have as large a response to 5% and 7% CO<sub>2</sub>. (B, C) *Lmx1b<sup>f/f/p</sup>* have a smaller response to an increase in ambient CO<sub>2</sub> and this is due to a smaller increase in breathing frequency. Reproduced with permission from the Society for Neuroscience: *Journal of Neuroscience* (Hodges *et al.*, 2008) 28: 2495–505, ©2008. To see the full color version of this figure please refer to the color plate at the back of the book. Copies produced via our print on demand service do not contain color plates; if your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

and *in vitro* (Severson *et al.*, 2003). The question arises whether this chemosensitivity plays any role in normal brain function. Since 5-HT neurons in the midbrain project to the forebrain, it would be expected that any effect they have would be seen as a change in forebrain function. Forebrain projections of 5-HT neurons are particularly abundant to the limbic system and the thalamus, where they play important roles in anxiety and arousal. As it turns out, hypercapnia has particularly strong effects in inducing dyspnea, a form of anxiety interpreted as suffocation, and arousal from sleep.

Intense dyspnea is induced by an increase in arterial  $PCO_2$  (Chonan *et al.*, 1990; American Thoracic Society, 1999). The dyspnea induced by hypercapnia occurs in part independent of any indirect effects on changes in respiratory motor output. For example, quadriplegic patients experience dyspnea when inspired  $CO_2$  is increased (Opie *et al.*, 1959; Banzett *et al.*, 1989). Similarly healthy, mechanically ventilated human subjects paralyzed with vecuronium develop dyspnea when exposed to an increase in inspired  $CO_2$  (Banzett *et al.*, 1990). There is other evidence indicating that changes in  $CO_2$  can induce dyspnea independent of changes in respiratory effort (Buchanan *et al.*, 2008), suggesting that there are direct effects of hypercapnia, presumably mediated by stimulation of  $CO_2$  chemoreceptors.

Functional imaging studies with positron emission tomography and functional magnetic resonance imaging have shown that hypercapnia activates multiple limbic regions of the brain (Buchanan *et al.*, 2008). Furthermore, SSRIs reduce anxiety and panic thought to be due to limbic activation (Hensler, 2006). Thus, the presence of diffuse projections from midbrain raphe nuclei to forebrain and limbic structures involved in dyspnea, and the influence of 5-HT on limbic function, supports the notion that direct projections from 5-HT neurons could mediate the sensation of dyspnea in response to hypercapnia.

Hypercapnia is also a potent arousal stimulus. In adult humans, hypercapnia induces arousal from both non-REM and REM sleep, but with a lower threshold for REM compared to non-REM (Berthon-Jones and Sullivan, 1984). In dogs, hypercapnia induces arousals from both non-REM and REM but does so more quickly and with a lower threshold in non-REM than in REM (Phillipson *et al.*, 1977). In lambs, repeated 60-second challenges with 8 percent  $CO_2$  greatly increase arousal probability compared with control conditions (Johnston *et al.*, 2007). It has previously been proposed that 5-HT neurons could contribute to this arousal response to hypercapnia (Washburn *et al.*, 2002; Severson *et al.*, 2003) since 5-HT neurons of the midbrain are chemosensitive and 5-HT causes conversion of thalamocortical activity from a sleep-like pattern to a waking pattern (Steriade *et al.*, 1993). Consistent with this

possibility, preliminary data from *Lmx1b<sup>fl/p</sup>* mice indicate that 5-HT neurons are required for the normally robust electroencephalographic and behavioral changes associated with arousal in response to hypercapnia (Buchanan *et al.*, 2007). It is possible that midbrain 5-HT neurons induce arousal in response to low levels of  $CO_2$ , whereas the same neurons induce anxiety and dyspnea at higher  $CO_2$  levels.

### The 5-HT system, ventilation and human disease

A variety of human diseases have been linked to abnormalities of the 5-HT system. Some of these are also associated with abnormalities of breathing and/or the response to hypercapnia. These include sudden infant death syndrome (SIDS), sudden unexplained death in epilepsy (SUDEP), sleep apnea, panic disorder and Parkinson's disease.

#### SIDS

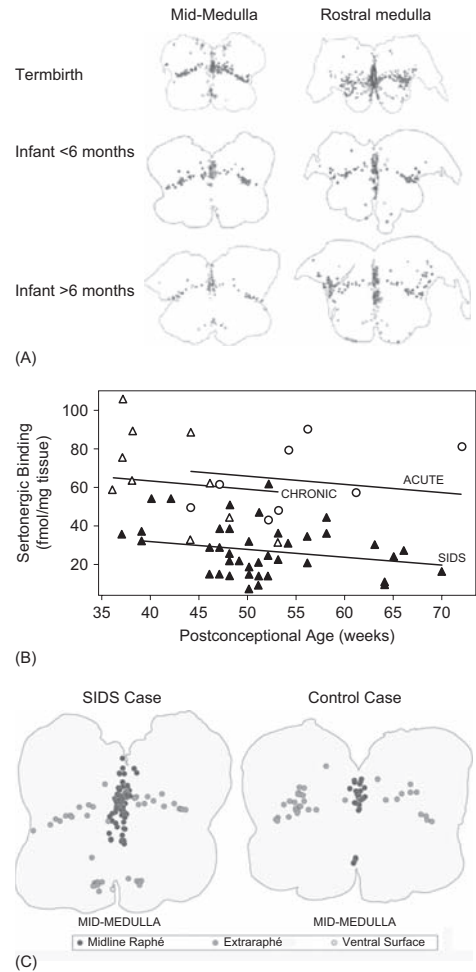

SIDS is the leading cause of mortality in infants between 1 month and 1 year of age in the developed world with an incidence of around 0.6 per 1000 (Kinney *et al.*, 2009), accounting for 6 deaths in the US every day. It is defined as 'the sudden and unexpected death of an infant under 12 months of age that is usually associated with a sleep period and remains unexplained after a complete autopsy, death scene investigation, and review of the clinical history' (Krous *et al.*, 2004). Based on the evidence at the time, Hunt and Brouillette proposed in 1987 that 'the most compelling hypothesis continues to be that SIDS is related to a brainstem abnormality in the neuroregulation of cardiorespiratory control' (Hunt and Brouillette, 1987). It is now known that a small subset of SIDS is due to mutations of cardiac ion channels that lead to long QT syndrome (Weese-Mayer *et al.*, 2007). However, the majority of cases are thought to be due to abnormal brainstem regulation of cardiac or respiratory function (Kinney *et al.*, 2001, 2005, 2009). Recognition that the majority of cases are found in the prone position, and the hypothesis that this causes airway obstruction, resulted in the 'Back to Sleep' campaign, which reduced the incidence of SIDS by 50 percent. Insight into the mechanisms of SIDS has also recently been advanced by the demonstration of abnormalities in the 5-HT system in four independent datasets of pathology material from SIDS cases (Kinney *et al.*, 2009). For example, there is a decrease in binding of lysergic acid diethylamide (LSD), a ligand for 5-HT<sub>1A-D</sub> and 5HT<sub>2</sub> receptors, in the medullary arcuate nucleus of SIDS infants compared to control cases. This nucleus is

of interest because it is homologous to chemosensitive fields of the ventrolateral medulla of cats (Filiano *et al.*, 1990), and because it contains cell bodies of 5-HT neurons (Figure 4A). It has also been found to be hypoplastic in a small number of cases of SIDS. Other regions containing 5-HT neurons also have decreased LSD binding in SIDS victims (Figure 4B) (Kinney *et al.*, 2009). It is now known that this decrease in 5-HT receptor binding is due to a decrease in 5-HT<sub>1A</sub> autoreceptors present on 5-HT neurons themselves, because there is also a decrease in binding of 8-OH-DPAT (Paterson *et al.*, 2006).

Recently it has been found that there is an increase in number of 5-HT neurons in the medulla of SIDS cases (Figure 4C), but that the majority of these neurons have an 'immature' morphology (Paterson *et al.*, 2006). It is not yet clear how these pathological changes relate to the function of the 5-HT system, but one possibility is that there is a delay in development of 5-HT neurons, possibly induced by environmental exposures or genetic factors (Weese-Mayer *et al.*, 2007; Kinney *et al.*, 2009). Environmental factors that have been identified include exposure to cigarette smoke and maternal use of alcohol (Moon *et al.*, 2007). Genetic factors include allelic variants of the promoter region of the gene for the 5-HT transporter (Weese-Mayer *et al.*, 2007). There may also be effects of sex hormones, since there is a higher incidence of SIDS in males compared to females, as well as differences in the pathology between genders in the raphe obscurus (Paterson *et al.*, 2006). Therefore, the working hypothesis is that the pathological changes in SIDS reflect a decrease in function of the 5-HT system, which causes abnormal respiratory output. If that is the case, then infants at risk may have abnormalities of breathing, cardiac function and thermoregulation similar to (but less severe than) the mouse models described above.

## SUDEP

Some epilepsy patients die unexpectedly without apparent cause. The incidence of this SUDEP has been estimated at 0.09 per 1000 person-years for a general population of epilepsy patients, and at 9.3 per 1000 person-years in high-risk epilepsy surgery candidates (Tomson *et al.*, 2008). That translates to 9.3 percent of the latter population that will die of SUDEP over 10 years. The epidemiology of SUDEP has many parallels with SIDS. For example, a subset of SUDEP cases also has mutations of long QT syndrome genes, but the majority are thought to be due to abnormalities of cardiorespiratory control (Ackerman, 2005; Tomson *et al.*, 2008; Johnson *et al.*, 2009). As with SIDS, patients are often found in bed,

**Figure 4** Sudden infant death syndrome (SIDS) is associated with abnormalities of the 5-HT system. (A) Developmental changes in the human medullary raphe nuclei at the mid- and rostral medullary levels. Blue dots, raphe 5-HT neurons; green dots, extra-raphe 5-HT neurons; red dots, 5-HT neurons on the ventral surface including the arcuate nucleus. Scale bar: 1 cm. (B) Tritiated LSD binding to 5-HT receptors is decreased in the raphe obscurus of infants that have died of SIDS. The scatter plot shows <sup>3</sup>H-LSD binding as measured with quantitative tissue receptor autoradiography in the raphe obscurus relative to postconceptional age for SIDS cases (solid triangles) compared to control infants that died of acute causes (open circles) or diseases that caused chronic hypoxia (closed circles). (C) Comparison of distribution of 5-HT neurons of a SIDS case and a control case. In the mid-line raphe of the SIDS infant there is an increased number of 5-HT neurons. and 71 percent are found in the prone position (Kloster and Engelskjøn, 1999). It is also more common in males. Recently it has been found that there is severe postictal respiratory depression in many epilepsy patients, with oxygen saturations dropping below 90 percent after 33 percent of seizures (Bateman *et al.*, 2008). This occurs even in complex partial seizures without generalization, so it is not due to loss of motor function (Figure 5A). Changes in respiratory function have also been seen in animal models of seizures (Johnston *et al.*, 1997; St-John *et al.*, 2006). SUDEP has been associated with abnormalities of 5-HT function (So, 2008). For example, in the DBA/2 mouse model of seizures, there is a high incidence

of postictal apnea and death, both of which are reduced after treatment with fluoxetine, a 5-HT reuptake inhibitor (SSRI) (Figure 5B) (Tupal and Faingold, 2006). Thus, it is reasonable to conclude that seizures may cause temporary dysfunction of 5-HT neurons due to invasion of the brainstem by electrical discharges, and this could cause respiratory arrest.

### Sleep apnea

The involvement of 5-HT neurons in control of breathing and the decrease in firing rate of 5-HT neurons during sleep (Jacobs *et al.*, 1990) suggest that airway obstruction in sleep apnea could be worsened in patients with defects in the 5-HT system. It is clear that motor neurons that innervate the airway receive serotonergic projections (Brandes *et al.*, 2006). There is evidence that a decrease in 5-HT release contributes to the decrease in airway tone during sleep in animals (Fenik *et al.*, 2005), although there is also evidence against this (Horner, 2008). Nonetheless, a subset of patients with sleep apnea improve with treatment by SSRIs (Hanzel *et al.*, 1991). It is possible that patients whose sleep apnea is due to a decrease in function of the 5-HT system may be more likely to respond to treatment with serotonergic drugs.

### Panic disorder

It has been proposed that panic attacks are due to false activation of a 'suffocation alarm' that is present in everyone and is mediated by neural circuitry that initiates a protective response to conditions that prevent adequate ventilation of the lungs (Klein, 1993; Papp *et al.*, 1993). Patients with panic disorder experience spontaneous episodes of severe dyspnea, hyperventilation, palpitations and anxiety. These panic attacks can be induced in many patients with panic disorder by exposure to elevated ambient CO<sub>2</sub> (Gorman *et al.*, 1994). For example, two breaths of 35 percent CO<sub>2</sub> is adequate to induce a panic attack in many panic disorder patients (Fyer *et al.*, 1987). There is no animal model of panic disorder, and the neural mechanisms of panic attacks in humans are poorly understood, but it is widely believed that defects in the 5-HT system contribute (Coplan *et al.*, 1992). For example, SSRIs are the first-line treatment for panic disorder patients. Thus it is reasonable to conclude that patients with panic disorder have an electrophysiological defect in 5-HT neurons that causes them to develop paroxysmal firing in response to levels of CO<sub>2</sub> that are not high enough to be activating in normal humans. This in turn would cause inappropriate activation of many neural circuits that are involved in the

**Figure 5** Some cases of sudden unexpected death in epilepsy (SUDEP) may involve postictal blunting of serotonergic respiratory drive. (A) Recording of oxygen saturation in a patient with a complex partial left temporal onset seizure. Despite the lack of secondary generalization there is severe and prolonged desaturation to 30 percent. The patient remained sitting the entire seizure. (B) Fluoxetine reduces postictal respiratory arrest in DBA/2 mice. All mice had respiratory arrest after audiogenic seizures. This was significantly reduced by fluoxetine treatment in a dose dependent manner. (A) Reproduced with permission from the Oxford University Press: *Brain* (Bateman *et al.*, 2008) 131 (Pt 12) 3239–45, ©2008. (B) Reproduced with permission from the Oxford University Press: *Epilepsia* (Tupal and Faingold, 2006) 47: 21–6, ©2006.

**Figure 6** Parkinson's disease involves the 5-HT system early and many patients have abnormalities of breathing and chemoreception. (A) Braak staging of neurodegeneration in idiopathic PD. Note that 'gain-setting nuclei', which includes the raphe nuclei, are involved earlier in the disease process than dopaminergic neurons of the substantia nigra. (B) Progression of disease in PD begins in the lower brainstem and progresses rostrally. (A) Reproduced with permission from Springer: *Cell Tissue Research* (Braak *et al.*, 2004) 318: 121–34, ©2004. If your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

response to hypercapnia, including respiratory, cardiac and limbic circuits (Buchanan *et al.*, 2008).

### Parkinson's disease

It has long been thought that Parkinson's disease (PD) is due to specific neurodegeneration of dopaminergic neurons of the substantia nigra, and that the symptoms are relatively limited to defects in motor control. However, that view has recently been drastically changed by the realization that most PD patients have a large constellation of non-motor symptoms that precede motor symptoms by many years (Lim *et al.*, 2009; Tolosa *et al.*, 2009). These symptoms include many forms of autonomic dysfunction, pain/sensory disturbances, sleep and mood disorders, and olfactory deficits. Consistent with these wide-ranging symptoms, it has recently been discovered that there are many pathological changes that precede degeneration of the substantia nigra, including in the enteric nervous system and medullary autonomic nuclei such as the dorsal motor nucleus of the vagus (Figure 6) (Braak *et al.*, 2003, 2004). The raphe nuclei are one of the earliest neuronal groups that degenerate (Braak *et al.*, 2004). This is relevant to the above discussion because a large percentage of PD patients complain of problems with breathing, including dyspnea in 40 percent of patients (Witjas *et al.*, 2002), and respiratory dyskinesia in many others. There is also blunting of the hypoxic ventilatory response in many PD patients (Onodera *et al.*, 2000), and the leading cause of death is pneumonia. It is possible that defects in 5-HT

neurons could contribute to some of these symptoms, and indeed there is some evidence that PD patients may benefit from adjunctive treatment with serotonergic drugs (Di Matteo *et al.*, 2008).

Each of these examples illustrates how understanding the role of 5-HT neurons in control of breathing and CO<sub>2</sub> sensation may lead to unexpected insights into the pathophysiology of a variety of human diseases that are not necessarily associated with breathing. There are additional examples for which a link may also exist, but where the exact relationship remains unclear, such as migraine headaches, hypercapnia-induced changes in cerebral blood flow, and hypocapnia-induced absence seizures. Defining these relationships through a better understanding of the role of 5-HT neurons in chemoreception will be an important goal for future work in these areas.

# Serotonin and Development<sup>1</sup>

Patricia M. Whitaker-Azmitia\*

*Department of Psychology, Stony Brook University, Stony Brook, New York*

**Abstract:** Serotonin is a key neurotransmitter in the adult brain, as well as a developmental signal in the developing brain. Serotonin itself is expressed very early in both human and rodent brain, and its receptors, enzymes and transporter sites are all overdeveloped initially, peaking in some cases in the first 2 years of life and in other cases in early adolescence. In either case, the serotonin system begins to decline by early adulthood. This early peak in activity reflects the developmental function of serotonin; however, even in the adult brain, serotonin is likely to play a role in maintenance and plasticity. As a developmental signal, serotonin acts in a variety of ways, depending on the developmental stage. Earliest on, serotonin acts in an autoregulatory manner, influencing the development of its own neurons. As brain development continues, serotonin begins to act in all subsequent stages – neurogenesis/neuroprotection, gliogenesis, migration and finally differentiation and maturation. Any factor which influences the amount of serotonin during development may result in enduring changes in the brain. In this regard, concerns have been raised regarding the effects of maternal stress or drug use during pregnancy. Understanding the role of serotonin in development has made significant contributions to the study of developmental disabilities, including fetal alcohol syndrome and autism.

**Keywords:** neonatal, fetal, neurogenesis, gliogenesis, synaptogenesis, ontogeny, neuroprotection, serotonin, development.

## Development of the serotonergic system

Although the number of serotonin neurons is very small in all species studied, once born, the neurons develop into the most widely spread neurotransmitter system in the brain. Serotonin is also one of the earliest developing neurotransmitter systems in the mammalian brain (Aitken and Tork, 1988; Lauder, 1990). During brain development, serotonin itself, as well as its associated enzymes, uptake sites and receptors, all reach peak levels before declining into adult values. This peak in serotonergic activity early in brain development reflects the dual role of serotonin in the brain – as a developmental signal and as a neurotransmitter. In the immature brain, significantly higher levels of serotonin are required in order to serve the developmental role, and any disruption can have serious consequences to the final mature brain. Thus, knowing the timing and means by which the serotonin system itself develops can be key to understanding much of adult brain function.

## Serotonin cell determination

Serotonin neurons appear early in development, mostly in two groups of nuclei in the anterior and posterior medulla which later become the well-recognized nine raphe nuclei, nuclei B5–9 (which includes the largest, the dorsal raphe) arise from the anterior group and B1–4 from the posterior group. Consequently, B5–9 project largely to cortical and some cerebellar targets, while B1–4 principally project to the spinal cord. Serotonin cell development, like all cells, is determined by both the cell's environment and its genome.

There appear to be distinct differences in the genetics of early development in the two clusters, and the anterior group forms slightly earlier than the posterior (Cordes, 2005). Serotonergic induction occurs in cell populations defined by Sonic hedgehog (Shh) (Hynes and Rosenthal, 1999), along the dorsal–ventral axes and FGF 4 in the antero-posterior axis in the posterior groups. The anterior group induction takes places through the positioning actions not only of Shh and FGF4, but also of FGF 8 (Ye *et al.*, 1998). Further, FGF 8 levels determine formation of dorsal or medial raphe nuclei, in the anterior group. The transcription factor Nkx2.2 is also involved in the generation of the posterior groups (Briscoe *et al.*, 1999).

Once the position of serotonin precursor cells is determined, other transcription factors are necessary to establish the actual serotonergic phenotype in the post-mitotic cells (Gaspar *et al.*, 2003). The principal transcription factor required to establish the neurochemical specificity of serotonin neurons (i.e., tryptophan hydroxylase and the serotonin transporter) is the ETS family factor Pet-1 (Hendricks *et al.*, 1999). Pet-1 is found in the entire extent of the raphe nuclei, but localized only to those cells which will express tryptophan hydroxylase. Conserved Pet-1 binding sites are found in the promoter regions of the specific serotonin neuronal markers – 5-HT1A receptor, the serotonin transporter (SERT), tryptophan hydroxylase and aromatic-L-amino acid decarboxylase (Hendricks *et al.*, 1999). Other important factors, including the homeobox gene *Lmx1b*, *Mash1*, *Gata2*, *Gata3* and *Phox2b*, form a ‘transcriptional network’ which further specifies differentiation (Alenina *et al.*, 2006).

### ***Development of the serotonin system in human brain***

In the human brain, serotonergic neurons are first evident in the brainstem by 5 weeks of gestation (Sundstrom *et al.*, 1993), and increase dramatically by the tenth week of gestation (Shen *et al.*, 1989; Kontur *et al.*, 1993; Levallois *et al.*, 1993), where they are found predominantly in the dorsal raphe nuclei (Shen *et al.*, 1989). Very early on, serotonin neurons are distributed in association with cranial nerve nuclei and reticular formation nuclei associated with respiration and blood pressure regulation (Kinney *et al.*, 2007). By at least 20 weeks of gestation (Kinney *et al.*, 2007) or as early as 15 weeks (Takahashi *et al.*, 1986), the typical organization of serotonin cell bodies into the raphe nuclei can be seen. The number of serotonergic cells shows a reduction as fetal development continues (Shen *et al.*, 1989). By birth, the highly regulated and important diurnal rhythm of serotonin is already present (Attanasio *et al.*, 1986).

The serotonin fibers reach the cortical anlage at 8 weeks of gestation, the subplate at 10 weeks of gestation and the cortical plate at 13 weeks of gestation (Verney *et al.*, 2002). At the same time, the serotonin transporter can be visualized in non-serotonergic fibres in thalamocortical processes (Verney *et al.*, 2002) in the interior capsule (between putamen and caudate), suggesting that serotonin is being produced and must be regulated in order for development to proceed. Synthesis of serotonin in the brain continues to increase throughout gestation and into the first 2 years of life, peaking at levels approximately twice that found in the adult brain at 5 years of age (Chugani *et al.*, 1999) and then declining to adult levels (Hedner *et al.*, 1986; Toth and Fekete, 1986).

Imaging studies of the serotonin transporter in developing neurologically typical children show a steady increase from 3 years of age to 18 years (Makkonen *et al.*, 2008), but by 20 years of age PET studies have shown that the serotonin transporter begins to decrease and continues to do so at the approximate rate of 10 percent per decade up until the eighth decade (Yamamoto *et al.*, 2002). A similar age-related loss of serotonergic tone, using endocrine challenge tests, has been reviewed and reported (Lerer *et al.*, 1999).

5-HT1A serotonin receptors are highest in the developing brain, estimated to be at gestational weeks 16–22 (Bar-Peled *et al.*, 1991; del Olmo and Pazos, 2001), and levels fall to that found in the young adult by birth (del Olmo *et al.*, 1998). There is a transient appearance of this receptor in the fetal and neonatal cerebellum, a region from which it is absent in the adult (del Olmo *et al.*, 1994). After the age of 20, PET studies show a decrease of 3.6–10 percent per decade of the 5-HT1A receptor in cortical regions; however, there is no loss in the raphe autoreceptor (Tauscher *et al.*, 2001), with the greater decline in females (Costes *et al.*, 2005). This pattern in the 5-HT1A receptor is therefore similar to the patterns found for serotonin terminals and serotonin levels. This is not surprising, since this is the receptor most closely associated with the developmental effects of serotonin. Moreover, this receptor has been localized in high numbers to immature astroglial cells, and much of serotonin’s actions on neuronal maturation may be through release of growth factors from astroglial cells.

5-HT2 receptors also show peak levels prenatally, but later than the 5-HT1A receptor, the 5-HT2A showing the highest level in raphe nuclei at midgestation (Zec *et al.*, 1996; Paterson *et al.*, 2004). The 5-HT2A receptor first appears in insular and temporal cortex by 25 weeks of gestation but does not peak in number until 31/32-gestation-week specimens, relatively late in the development of cortex (Wai *et al.*, 2008). In human PET studies, the number of 5-HT2A receptors dramatically decreases beginning at the age of 20 (Sheline *et al.*, 2002).

Thus, serotonin fibers are growing into the human cortex, as migration and differentiation are taking place. Moreover, the amount of serotonin begins to decrease by age 20, when the final stages of brain maturation are thought to have occurred.

### ***Development of the serotonergic system in rodent models***

In rodent brain, a very similar pattern of development is seen – that is, an early and robust development followed by a decline as the animal reaches adolescence.

Serotonergic cells are first identifiable at gestational day 12 (GD 12), as two groups of cells in the midline of the rhombencephalon (Hendricks *et al.*, 2003), with the rostral group evident earlier (Zhou *et al.*, 2000). Genesis of serotonin cells continues until GD 18 (Hansson *et al.*, 1998). The caudal group (designated B1–5) becomes the descending serotonin system of the raphe pallidus, raphe magnus, raphe pontis and raphe obscurus. The rostral group (B6–8) becomes the ascending serotonin system of the dorsal and median raphe nuclei (Lauder *et al.*, 1982; Lauder, 1985, 1990).

Initial axonal elongation is evident as early as GD 12 and continues until GD 16 (Hansson *et al.*, 1998; Zhou *et al.*, 2000) when axons enter the medial forebrain bundle and reach the basal forebrain and hippocampus (Hansson *et al.*, 1998), stria terminalis, hypothalamus, dorsal thalamus, cingulate cortex, superior olivary nucleus and cochlear nucleus (Narboux-Neme *et al.*, 2008). Serotonin projections continue to grow, traveling along pre-existing fiber tracts on GD 16–19 and arriving in the frontal cortex by GD 20 (Lidov and Molliver, 1982; Wallace and Lauder, 1983; Zhou *et al.*, 2000) in rat. Development in mice is essentially the same as in rats (Brüning *et al.*, 1997). Although serotonin axons reach target areas by birth, the final innervation arborization occurs robustly up until postnatal day (PND 21). In many cases, the terminal density decreases after that point (Hansson *et al.*, 1998). In somatosensory cortex the peak is even earlier, and is decreased to adult levels by 21 days, suggesting a very important role for serotonin in development of this region (D'Amato *et al.*, 1987). It is during this time of terminal arborization that serotonin also reaches its highest brain levels in rodents, much like the first 2–5 years of human life, and also at the time when synaptogenesis is at its peak. As in human brain, there is a transient expression of the serotonin transporter in cells which are not serotonergic. In particular, this has been observed in thalamocortical projections to sensory cortex (Brüning and Liangos, 1997), where serotonin is thought to play a role in barrel field formation (see below).

Similar to human brain, amongst the serotonin receptors examined, the 5-HT<sub>1A</sub> appears to be the receptor which shows the earliest appearance in development and can be transiently expressed in brain regions from which it is later absent, including the cerebellum (Daval *et al.*, 1987). The receptor is found densely by GD 15 in mice, in the thalamus, hippocampus and in cortex, in a medial to lateral gradient as development takes place (Bonnin *et al.*, 2006). In the developing hippocampus of rats, the 5-HT<sub>1A</sub> receptor is found in virtually all neurons once neurogenesis is complete (Patel and Zhou, 2005). Astroglial cells transiently express high amounts of this receptor postnatally, further suggesting that the role of serotonin in

development may be in part mediated through effects on the astroglial cell (Whitaker-Azmitia *et al.*, 1990a; Patel and Zhou, 2005). Early work showed that these receptors could undergo plastic changes if animals were treated prenatally with serotonin receptor agonists (Whitaker-Azmitia *et al.*, 1987).

5-HT<sub>2</sub> receptors also show a pattern similar to human development. The receptor peaks later than the 5-HT<sub>1A</sub>, reaching adult levels postnatally (Basura and Walker, 2000; Basura *et al.*, 2008).

## Role of serotonin in brain development

Over the course of development, the actions of serotonin clearly change as well. Early on serotonin's role will be involvement in cell survival, and later, as the brain matures, serotonin will play a role in migration and differentiation. It is also likely that, even in the adult brain, serotonin will play a role in synaptic maintenance and plasticity, in many cases by the same mechanisms used in development. The following sections are arranged by developmental properties over time, and combine both human and animal studies.

### Autocrine/autoregulatory effects

In animal studies, one of the earliest observed effects of serotonin on brain development was that it could inhibit the outgrowth of serotonin-producing neurons themselves (Whitaker-Azmitia and Azmitia, 1986a; Haydon *et al.*, 1987; Diefenbach *et al.*, 1995; Goldberg, 1998). Thus, developmental treatment with a variety of drugs which increase serotonin during development, including agonists (Shemer *et al.*, 1988, 1991), releasers (Akbari *et al.*, 1992), MDMA (Koprich *et al.*, 2003), monoamine-oxidase inhibitors (MAO-I) (Whitaker-Azmitia *et al.*, 1994) and uptake inhibitors (Cabrera-Vera *et al.*, 1997; Cabrera-Vera and Battaglia, 1998), have all been shown to decrease the serotonin activity in the adult brain.

Cell cultures of serotonin neurons derived from embryonic raphe neurons from mice lacking 5-HT<sub>1A</sub> or 5-HT<sub>1B</sub> receptor show that both of these receptors, but particularly the 5-HT<sub>1A</sub> receptor, show tonic inhibition of serotonin neuronal survival. Specifically, inhibition of cAMP by the autoreceptor 5-HT<sub>1A</sub> appears to be involved in inhibition of development (Rumajogee *et al.*, 2004).

Two recent studies using serotonin reuptake inhibitors during development show that there are behavioral changes associated with the decreased serotonergic outgrowth (Ansorge *et al.*, 2008; Popa *et al.*, 2008). Studies in 5-HTT<sup>-/-</sup> mice show a similar effect, with a 50 percent

loss of serotonin neurons overall in the knockout animals (Lira *et al.*, 2003) and resultant behavioral changes such as increased measures of depression (Lira *et al.*, 2003) and anxiety (Holmes *et al.*, 2003). These behavioral changes in the 5-HTT<sup>-/-</sup> mice are suggested to be due to the effects of increased 'serotonin tone' in early development, and if mice are treated with PCPA or a 5-HT1A antagonist from PND 5-28, the depression and anxiety improve. Again, this suggests a role for the 5-HT1A receptor in inhibition of serotonergic development (Alexandre *et al.*, 2006).

This autoregulatory developmental effect of serotonin may play a role in the symptoms of autism, as children with autism often have an increased blood level of serotonin. This could access the brain early in development, before the blood-brain barrier is complete, and cause loss of serotonin terminals (Whitaker-Azmitia, 2005). Recent findings show that there is indeed a loss of serotonin terminals in autism (Chugani *et al.*, 1997, 1999; Makkonen *et al.*, 2008).

### Neurogenesis/neuroprotection

Although serotonin fibers are present in cortex during late stages of neurogenesis in both humans (Sidman and Rakic, 1973) and rodents, there is very little clear evidence that serotonin plays a direct role in increasing cell proliferation. Rather, the earliest work by Jean Lauder, using parachlorophenylalanine (PCPA)-depletion of serotonin and thymidine incorporation to determine the effects of serotonin on development, found that serotonin actually ceased cell division by influencing the onset of differentiation (Lauder and Krebs, 1978; Lauder *et al.*, 1981; Lauder, 1983).

Similar work by Vitalis *et al.* (2007) treated developing rat fetuses from GD 12 to 17 with PCPA and found no change in BrdU incorporation or changes in cell cycle markers at GD 16.5 or 17.5, indicating no direct effect on cell proliferation. However, these authors have introduced the possibility that any decrease in cell number that may be observed could be due to the neuroprotectant role of serotonin, and thus any apparent loss in cell number in a serotonin-depleted animal may actually be due to increased apoptosis (see below). Indeed, in a similar PCPA-depletion study by Khozhai and Otellin (2006), the authors found that as the animals aged, there was a greater number of cells dying.

The case in the hippocampus may be different, where there is evidence that serotonin may play a limited role in neurogenesis of granule cells in the adult brain. Brezun and Daszuta (1999) found that depleting serotonin with the toxin 5,7 dihydroxytryptamine in adult rats decreased the

number of BrdU-labeled granule cells in the dentate gyrus, and that transplanting fetal raphe cells into the hippocampus restored neurogenesis (Brezun and Daszuta, 2000). It has been suggested that the 5-HT1A receptor plays a role in neurogenesis in the hippocampus (Gould, 1999).

As a result of these studies on adult hippocampal neurogenesis, it had been suggested that serotonergic drugs such as the selective serotonin reuptake inhibitors (SSRIs) also increase neurogenesis in the adult brain, and that this mechanism might explain antidepressant therapeutic effects (Santarelli *et al.*, 2003; Marcussen *et al.*, 2008). However, recently studies have failed to support this observation (Cowen *et al.*, 2008; Huang *et al.*, 2008; Navailles *et al.*, 2008).

### Gliogenesis and maturation

Serotonin plays a role in generating and maturing astroglial cells. One important aspect of this function is the release of the calcium-binding protein S100B from astroglial cells into the neuropil. Once released, S100B may actually be the mediator of many of the effects of serotonin on later brain development, such as differentiation and maturation of neurons.

The earliest studies of Lauder *et al.* (1982) combining thymidine incorporation and serotonin immunohistochemistry found that developing serotonin axons were closely associated with proliferating astroglial cells, and it was suggested that growing serotonin axons release trophic factors from these cells as they grow, which in turn matures neighboring neurons (Lauder, 1985). When rat pups are depleted of serotonin prenatally (with PCPA) there are fewer GFAP-positive astroglial cells as adults (Khozhai, 2006), while prenatal treatment with a 5-HT1A agonist increases glial number (Tajuddin *et al.*, 2003). 5-HT1A overexpressing mice show increased S100B positive cells in the cortex, striatum and hippocampus at PND 15.5 (Deng *et al.*, 2007). In adult rat, SSRI-treatment prevents stress-induced loss of astroglial cells (Czéh *et al.*, 2006) and may promote gliogenesis (Manev *et al.*, 2003). These animal findings have led to the suggestion that SSRIs may play a role in improving outcomes in neurological disorders, including epilepsy, stroke and Alzheimer's disease (Mostert *et al.*, 2008).

Astroglial cells express a number of serotonin receptors as well as the serotonin transporter (Whitaker and Warsh, 1983; Whitaker-Azmitia and Azmitia, 1986b). The 5-HT2 receptor is expressed, and, through this receptor, serotonin plays a role in release of Glial-cell line Derived Neurotrophic protein (GDNF) – a protein which serves as a neuroprotectant and neuronal survival factor (Tsuchioka *et al.*, 2008).

The high-affinity 5-HT<sub>1A</sub> receptor is also expressed on astroglial cells, in higher numbers in the immature cell and lower numbers as the cell matures. This may account for many of the transiently expressed serotonin receptors in whole brain. Some studies have suggested that SSRIs also influence release of S100B, and thereby exert their therapeutic effect (Tramontina *et al.*, 2008). Moreover, the 5-HT<sub>1A</sub> receptor is responsible for regulating the release of the very important cytokine, S100B.

In cell culture studies, treatment with a 5-HT<sub>1A</sub> agonist increases maturation of astroglial cells, taking on a stellate mature phenotype while releasing the neurotrophic factor, S100B (Azmitia *et al.*, 1990; Whitaker-Azmitia *et al.*, 1990a). S100B is a member of the EF-hand family of calcium-binding proteins, and plays a role in many cells by virtue of its ability to regulate both intra- and extracellular calcium. S100B also influences cellular function by binding to the cell surface receptor RAGE (receptor for advanced glycation endproducts). Amongst its known functions, S100B induces neurite outgrowth and prevents apoptosis. However, at higher concentrations and after brain trauma S100B can lead to increased cell death and advanced aging (Donato, 2003, 2007; Rothermundt *et al.*, 2003). Thus, serotonin has been suggested to play a role in both development and plasticity through regulation of S100B (Whitaker-Azmitia and Azmitia, 1994), and serotonergic regulation of this factor can be key to normal brain function.

### Apoptosis

Apoptosis (programmed cell death) is an important part of development, as the maturing brain overproduces neurons and many must be removed as a normal course of development. In the human brain, approximately 50 percent of neurons are removed immediately prior to birth (reviewed in Andersen, 2003). Serotonin reduces apoptosis in the developing brain. For example, in serotonin transporter knockout mice, the higher levels of serotonin lead to decreased cell loss in the striatum, thalamus, hypothalamus, cortex and hippocampus (Persico *et al.*, 2003). Neuronal cell lines transfected with the 5-HT<sub>1A</sub> receptor show greater survival (Fricker *et al.*, 2005).

Apoptosis can be induced in developing cells in a variety of ways. In cell culture, 5-HT<sub>1A</sub> receptor agonists inhibit apoptosis induced by ethanol (Lee *et al.*, 2008) or serum deprivation (Ahlemeyer *et al.*, 1999). Serotonin may also protect against apoptosis in the mature brain, and similar findings can be observed in animal models, where a 5-HT<sub>1A</sub> agonist is neuroprotective against ischemia (Bode-Greuel *et al.*, 1990; Bielenberg and Burkhardt, 1990) and NMDA-induced excitotoxicity (Oosterink *et al.*,

1998; Madhavan *et al.*, 2003). Removal of serotonin prior to the ischemia model increases damage (Nakata *et al.*, 1997). In an animal model of myocardial infarction, an SSRI inhibited apoptosis (Wann *et al.*, 2008). In some cases, the neuroprotective effect of serotonin is not directly on the neuron, but rather through the effects of serotonin 5-HT<sub>1A</sub> receptors releasing the astroglial protein S100B (Ahlemeyer *et al.*, 2000; Brewton *et al.*, 2001; Ramos *et al.*, 2004).

### Migration

Once cells are born, they must move (or migrate) to their final position in the brain before differentiation can take place. In human cortex, migration is complete by 26 weeks of gestation and the cortical layers are identifiable (Sidman and Rakic, 1973). At this time serotonin fibers are already in place, and serotonin may play a role in cortical layering. In mouse tissue culture models, serotonin inhibits interneuron migration, an effect blocked by a 5-HT<sub>6</sub> receptor antagonist. These same neurons are also disrupted in the 5-HTT knockout mouse (Riccio *et al.*, 2008). Treatment with the non-receptor selective serotonin agonist 5-methoxytryptamine (5-MT) during gestation causes a decrease in the amount of reelin produced by Cajal-Retzius cells of the cortex. Reelin, a glycoprotein associated with extracellular matrix, is involved in cortical column formation (Quattrocchi *et al.*, 2002), and the 5-MT-treated animals also showed pronounced disturbances in columnar formation (Janusonis *et al.*, 2005). Interestingly, deficits in reelin have been reported in autism (Fatemi *et al.*, 2005), which is often thought to be related to both cortical disturbed development and serotonin dysregulation.

### Axonal elongation

Once in place, neurons undergo the final steps in differentiation, axonal elongation, and synaptogenesis and dendritic elaboration. In rodent models, much of the axon elongation influenced by serotonin appears to be in sensory systems, and occurs in the first week of neonatal life. In humans, this corresponds to the final trimester of gestation.

For axonal elongation, the most striking role of serotonin is in the development of thalamocortical efferents – cells that do not express serotonin, but which express, transiently, the serotonin transporter. Thus, these axons appear to grow to specific sites in the cortex by responding to and controlling levels of serotonin in the neuropil of already developed cells (Cases *et al.*, 1996). Most of the

work in this area suggests that serotonin's largest influence is at PND 0–8 in the rat, a time when serotonin would be innervating virtually all of its targets, and a great deal of serotonin could be released from axonal varicosities by volume transmission (Zhou *et al.*, 2005). Excess serotonin leads to loss of the typical barrel-like patterns of cells in somatosensory cortex (Cases *et al.*, 1996; Lieske *et al.*, 1999), and a greater percent of the cortex is taken up by thalamic projections (Lane *et al.*, 2006). 5-HT1B receptors appear to be the predominant receptor involved in the control of thalamocortical outgrowth (Lotto *et al.*, 1999; Bou-Flóres *et al.*, 2000; Salichon *et al.*, 2001). Developing neonatal rat pups depleted of serotonin by tryptophan depletion show a delay in removing excess or misplaced connections in retinotectal projections (González *et al.*, 2008), and a similar role for serotonin has recently been described for ascending auditory pathways (Thompson, 2008). Thus, these studies all show a role for serotonin in the fine tuning of tactile, auditory and visual connections.

Terminal elaboration of serotonin neurons has an important relationship with developing dopamine terminals. It has been shown in animal studies that depletion of dopamine early in development leads to hyperinnervation by serotonin terminals (Basura and Walker, 1999, 2000), while developmental treatment with a dopamine D1 agonist decreases serotonin terminal growth (Whitaker-Azmitia *et al.*, 1990b). This interaction between monoamines has been suggested to play a highly significant role in 'miswiring' of the cortex, leading to psychopathologies (Benes *et al.*, 2000).

### *Synaptogenesis and dendritic elaboration*

The final step in development in which serotonin plays a role is in synaptogenesis and dendritic elaboration. Since this is the developmental process that actually takes place throughout life, serotonin's effects can last lifelong, and indeed there are animal studies showing that serotonin is an important synaptic maintenance factor, and indications that serotonergic drugs such as SSRIs may exert their pharmacological action by improving synaptic density.

In humans, synaptogenesis begins in midgestation (Huttenlocher *et al.*, 1983) and peaks at approximately 2 years of age (Chugani *et al.*, 1987). At 2 years, synaptogenesis and dendritic elaboration still continue at a high rate, but begin to slow down into adolescence and adulthood. This time-course coincides with what is known about the levels and activity of the serotonin system. Serotonin may influence synaptogenesis, directly through stimulation of 5-HT1A receptors, or through release of the trophic factor S100B (Azmitia, 2001).

The studies described below have shown effects for serotonin at four ages – fetal rat, which approximates midgestation in humans; neonatal rat, which represents the final trimester of gestation in humans; more than 1 week of age but less than 3 in rats, representing the first two years of human life; and, finally, adult studies. The pattern of effects on synaptogenesis varies with the critical time of depletion, with the earliest time showing the most long-lasting effects.

#### *Fetal rat, midgestation human*

PCPA depletion of serotonin from GD12–17 produces fewer dendrites in pyramidal neurons in layers III and V of somatosensory cortex which lasts into adulthood (Vitalis *et al.*, 2007). It appears that the 5-HT1A receptor is important, since in cultures of cerebellar Purkinje cells (Kondoh *et al.*, 2004) or hippocampal cells (Nishi *et al.*, 1996), synaptogenesis is increased by a 5-HT1A agonist.

#### *Neonatal rat, third trimester human*

Transient depletion of serotonin (by PCA or the selective 5-HT1A antagonist NAN-190) beginning at PND 3 shows that the 5-HT1A receptor plays a role in promoting synaptogenesis in dentate gyrus granule cells, particularly synaptic connections to dendritic spines. However, in this case the normal synaptic density is recovered by PND 60, suggesting it is delay in maturation rather than the permanent loss seen in animals depleted earlier in development. If serotonin is removed permanently beginning at PND 3 with the selective neurotoxin 5,7-DHT, dendritic development does not recover (Faber and Haring, 1999). Infusing the animals at this age with an antibody against S100B also shows a loss of synapses, which is not additive to the effects of a 5-HT1A antagonist (Wilson *et al.*, 1998). All of this shows that serotonin 5-HT1A-mediated release of S100B beginning at PND 3 (or the last trimester of human pregnancy) promotes synaptogenesis in the hippocampus. If serotonin levels are temporarily decreased, there is later recovery. If serotonin does not recover, there is also no recovery in synaptic density.

#### *1–3 weeks rat: first 2 years of human life*

Depletion of serotonin with PCPA from PND 10–20 leads to loss of presynaptic (synaptophysin) and dendritic markers (MAP-2) in the hippocampus of adolescent animals. As the animals age, there is recovery of presynaptic markers, but no improvement of the dendritic density. In the aged animal there is overgrowth of presynaptic elements, suggesting that a reactive synaptogenesis takes place over time (Mazer *et al.* 1997).

### Adult

Studies in adult animals show that the role serotonin plays in synaptogenesis continues in the form of synaptic maintenance into adulthood. PCPA depletion of serotonin in adult animals causes loss of synapses in all CA1, CA3 and granule layer cells (Matsukawa *et al.*, 1997), a loss of the dendritic marker MAP-2 throughout the hippocampus (Whitaker-Azmitia *et al.*, 1995), and a loss of neurofilaments of axons within the hippocampus (Ramos *et al.*, 2000). In adult female rats, PCPA decreases dendritic spine density in the hippocampus, independent of hormonal effects (Alves *et al.*, 2002). In the cortex, this depletion causes an estimated 39–50 percent loss of synapses (Chen *et al.*, 1994). In studies using PCA depletion of serotonin, loss of dendritic and synaptic markers can be seen not only in the hippocampus, but also in the hypothalamus and cortex (Azmitia *et al.*, 1995). Synaptic maintenance is through the 5-HT1A-mediated release of S100B. In 5-HT-depleted animals S100B can be seen to accumulate within the astroglial cell rather than being released into the neuropil (Ramos *et al.*, 2000), and treatment with a 5-HT1A agonist can reverse the synaptic loss (Azmitia *et al.*, 1995).

### Environmental effects on the development of serotonin

Many of the animal studies discussed above show that changing the levels of serotonin during development changes not only brain morphology but also behavior – in particular, lifelong alterations in behaviors modeling human anxiety (Borella *et al.*, 1997; Holmes *et al.*, 2003; Hohmann *et al.*, 2007; Cannizzaro *et al.*, 2008), autism (Kahne *et al.*, 2002; McNamara *et al.*, 2008), depression (Lira *et al.*, 2003; Vataeva *et al.*, 2007) and aggression (Farabollini *et al.*, 1988; Whitaker-Azmitia and Azmatia, 1994). These observations make it very important to know what variables during development affect serotonin, as these may be predisposing factors to psychopathology in later life.

Many external factors have been shown to interfere with the development of the serotonin system, including hypoxia (Shiraishi *et al.*, 2008; Strackx *et al.*, 2008), diet (Gonzalez-Burgos *et al.*, 1996; Feria-Velasco *et al.*, 2002; Himpel *et al.*, 2006; O'Reilly *et al.*, 2007; Pôrto *et al.*, 2008; Serfaty *et al.*, 2008), infections (Winter *et al.*, 2008), and environmental toxins such as pesticides (Garcia *et al.*, 2001; Aldridge *et al.*, 2005) and heavy metals. However, the most urgent concerns regarding potential damage to the serotonin system and long-term psychopathology are those centered on the effects of stress and of prenatal drug exposure.

### Stress

Stress-induced chronic activation of the hypothalamic–pituitary–adrenal axis has effects on the serotonergic system of the mature brain (Lanfumey *et al.*, 2008). For example, restraint models of stress raise corticosterone levels and desensitize the 5-HT1A receptor (Mendelson and McEwen, 1991), and decrease serotonin release. Some of the loss of the 5-HT1A receptor may be on astroglial cells, decreasing S100B support for other cells (Nishi and Azmitia, 1996). The effects of glucocorticoids on the serotonin system have been proposed to be the basis of stress-induced depression in the mature brain. The developing brain may be even more vulnerable to stress-induced damage, and the consequences longer lasting (McEwen, 2003).

Prenatal stress or treatment with dexamethasone from GD 15–21 causes decreased synaptic number and decreased serotonin in the hippocampus into adulthood (Muneoka *et al.*, 1997), and studies looking at various times of stress suggest that this is the time of greatest vulnerability prenatally in rodents (Peters, 1986). Rats born following *in utero* stress also have decreased 5-HT1A receptors in the hippocampus (Van den Hove *et al.*, 2006a). Pups born to adrenalectomized mothers show increased serotonin in the cortex and hippocampus at PND 1 and 8, but a decrease at PND 22 (Leret *et al.*, 2004). This could reflect an overgrowth of serotonin terminals in the absence of glucocorticoids, followed by the autoregulatory removal of excess serotonin terminals. Prenatal stress also decreases hippocampal content of S100B, suggesting that increased levels of corticosterone decrease S100B, resulting in lower levels of serotonin (Van den Hove *et al.*, 2006b).

Later in development, removal from the dam (Matthews *et al.*, 2001; Veenema *et al.*, 2006) or post-weaning social isolation both lead to a permanent loss of serotonin terminals in the hippocampus (Whitaker-Azmitia *et al.*, 2000). In the rodent *Octodon degus*, early deprivation leads to a loss of serotonin fibers in the hippocampus, but an apparent increase in the amygdala. This shows the importance of emotional experience in setting up serotonergic networks (Gos *et al.*, 2006).

In human infants, prenatal maternal levels of cortisol are correlated with lower levels of serotonin in the infant (Field *et al.*, 2003), and maternal depression during pregnancy also leads to loss of serotonin in the infant (Field *et al.*, 2004). However, at later times in development, massaging or stroking the infant or adolescent human increases blood serotonin (Field, 2002), suggesting that some of the loss of serotonin in rodent isolation studies may be due to loss of physical contact with parents or peers.

## Drugs

Many drugs exert their effects through the serotonergic system and thus would be expected to have an effect on the developing neurons themselves, at least in part through the autoregulatory/autocrine effects described above. For example, cocaine and MDMA would be expected to have serious effect on brain development by virtue of their effect on serotonin, and in animal studies, they do. However, greater concern should be placed on those substances more commonly taken during pregnancy – alcohol and the SSRI antidepressants. As well, since human brain development spans a long period of time – at least up to 20 years of age – the use of these substances even into adolescence should be considered carefully.

The most common non-genetic form of mental retardation continues to be that associated with fetal alcohol syndrome (FAS), and both animal and human studies show a role for alcohol-induced deficits in the serotonin system, and thus of serotonin regulation of brain development, in this condition. Treatment of animals at a very young fetal age (before serotonin neurons are born) with alcohol leads to a loss of both ascending and descending serotonin neurons (Sari and Zhou, 2004). This early exposure may reflect the increased incidence of sudden infant death (SID) in FAS (Kinney *et al.*, 2003; Zhou *et al.*, 2008). At later times of treatment (E11–15), although serotonin cell number is not affected, the number of terminals is decreased in the adult. This loss of serotonin fibers also results in the expected concomitant loss of maturation of regions along the pathway of the developing serotonin axons (Zhou *et al.*, 2005). This loss of neurons can be prevented by concomitant treatment with S100B or a 5-HT<sub>1A</sub> receptor agonist (Druse *et al.*, 2007), which blocks the alcohol-induced apoptosis of neurons (Druse *et al.*, 2006).

In human *post-mortem* studies, using tissue from children dying of SIDS, a significant loss of serotonin functioning in medullary nuclei was found in those children exposed to alcohol *in utero* (Kinney *et al.*, 2003). SPECT image analysis of the serotonin transporter in children with FAS show decreased transporter, suggesting loss of serotonin terminals (Riikonen *et al.*, 2005).

The use of antidepressants during pregnancy is an ongoing controversy, but epidemiological studies show that as many as 5 percent of women do take an antidepressant during pregnancy (Oberlander *et al.*, 2006). Antidepressants do not cause typical teratogenic effects on organ formation, and many women do need continual treatment during pregnancy. However, the long-term outcomes in terms of behavioral and neurochemical teratogenicity are not known, and animal studies suggest there may be persisting effects.

Many animal studies have looked at the effects of developmental exposure to antidepressants on the serotonin system in adults. In most cases, these studies have shown a reduction of serotonin (Hilakivi *et al.*, 1987; Feenstra *et al.*, 1996; Vijayakumar and Meti, 1999) or serotonin transporter (Hansen and Mikkelsen, 1998; Whitaker-Azmitia *et al.*, 2004; Maciag *et al.*, 2006) in the adult brain. This loss of terminals is what would be expected, as increased serotonin *in utero* could lead to the autoregulatory loss of serotonin terminals. Loss of serotonin in the mature brain following neonatal exposure to antidepressants has the expected behavioral changes – principally depressive-like symptoms (Hilakivi and Hilakivi, 1987; Fernandez-Pardal and Hilakivi, 1989; Vogel *et al.*, 1990; Velazquez-Moctezuma and Ruiz, 1992; Hansen *et al.*, 1997).

Thus, animal studies would predict that exposure to antidepressants during development would lead to loss of serotonin as adults and the behavioral phenotype of depression.

In the first few weeks of life, children exposed *in utero* to antidepressants do show a specific behavioral syndrome which is thought to be related to antidepressant withdrawal. In the early neonatal period, the exposed infants show irritability, tremor, restlessness and rigidity (Nordeng *et al.*, 2001; Zeskind and Stephens, 2004; Sanz *et al.*, 2005). Some studies show respiratory distress (Oberlander *et al.*, 2004). At 3 months of age, there is an altered HPA stress response (Oberlander *et al.*, 2008). The severity of this syndrome has been inversely correlated with decreased 5-HIAA in cord blood, suggesting that the exposed infants have decreased serotonin (Laine *et al.*, 2003). A study in newborn blood also indicates a loss of serotonin (Anderson *et al.*, 2004). Unfortunately there are no published studies on children older than 4 years, who do have subtle motor changes (Casper *et al.*, 2003), making it difficult to know whether or not the children will develop psychopathology related to low serotonin.

## Summary

Serotonin plays an important role in development of the human brain. Unfortunately, there are many factors which can alter the levels of serotonin during development. These changes in serotonin at critical times can lead to lifelong changes in mental functioning and may underlie serious psychopathology, including depression, anxiety and autism. However, knowing the role serotonin plays at crucial periods may also enable the therapeutic use of serotonergic agents, to restore appropriate development.

# Serotonin and Basal Sensory–Motor Control

Robert J. Carey\*

*VA Medical Center, and SUNY Upstate Medical University, Syracuse, New York*

**Abstract:** This chapter provides a brief synopsis of the essential role of brain serotonergic neurons in the integration of sensory input and motoric output. Although serotonin neurons are proportionally small numerically in the brain, the serotonin neurons have anatomical communication with virtually all neurons in the brain. For sensory–motoric function, the serotonin neurons have a particular prominence in that they densely project to primary sensory cortices and to cranial and spinal motor neurons. By virtue of this anatomical position at the entrance to and exit from brain and spinal cord, the serotonergic system is uniquely situated to modulate behavior across the full spectrum of the sleep–wakefulness cycle.

## Introduction

Serotonin-containing neurons represent a phylogenetically very old neurotransmitter system. The serotonin (5-HT) neurons are located in clusters of raphe nuclei which encompass areas from the midbrain to the medulla. While the total number of serotonin (5-HT) neurons is small relative to total neuronal cells in the brain (e.g., approximately 20,000 in rat brain), the axons of these cells have a massive number of collaterals so that virtually the entire brain and spinal cord receive 5-HT innervation (Steinbusch, 1981; Jacobs and Azmitia, 1992). Consistent with the rostral/caudal distribution of 5-HT raphe nuclei, the caudal pontine and medullary clusters send projections to the cerebellum, medulla and spinal cord, whereas the midbrain raphe nuclei innervate the forebrain. In keeping with the descending projections to the medulla, the 5-HT neurons have a substantial impact on basic functions related to respiration, thermal regulation and cardiovascular function. Projections from 5-HT nucleus raphe obscurus and ventral lateral medullary neurons project extensively to the ventral horn of the spinal cord and profusely innervate  $\alpha$ -motor neurons, thereby impacting substantially upon motoric function (Skagerberg and Bjorklund, 1985). More elusive in terms of function are the forebrain projections of the dorsal and median raphe nuclei situated in the midbrain reticular formation. These 5-HT axons project to neo- and paleocortex as well as subcortical striatal and limbic nuclei (Fallon and Loughlin, 1987). Not surprisingly, perturbations in the forebrain 5-HT have been implicated in several diverse functions, including cognition, memory, aggression, feeding

and reproduction (Brown and Linnola, 1990; Spoont, 1992; Lucki, 1998; Vanderwolf, 1998; Birger *et al.*, 2003). Such complex behavioral processes encompass interactions among many neuronal systems involving other neurotransmitters as well as peptides. Clearly, 5-HT systems are contributory to a variety of important behavioral functions. In linking serotonin and the serotonergic neural network to behavior, it is necessary to recognize that the underlying foundation of behavior is sensory–motor integration and that the serotonergic system is anatomically organized to play a major integrative role. In an effort to better define this serotonergic role in sensory–motor integration, we will initially consider some methodological problems and then focus upon several key observations which offer a potential unifying conceptual framework for the role of serotonin in sensory–motor function.

## Methodological considerations in brain/behavior analyses

A basic approach to a functional analysis of neurotransmitter systems is to perform experimental manipulation that selectively impairs neuronal activity in a single neurotransmitter system and assess the impact upon behavior. We will briefly examine basic issues that need to be considered in terms of linking 5-HT alterations to behavior. For example, the recent utilization of ‘knockout’ mouse preparations has provided one approach. While an animal model lacking 5-HT neurons is non-viable, it is possible to create viable knockouts lacking in particular 5-HT receptor subtypes (e.g., the 5-H<sub>1B</sub> receptor) (Rocha *et al.*, 1998; Sora *et al.*, 2001). Although behavioral changes can be observed in these preparations, the impact cannot be easily ascribed to the loss of a specific receptor

\*E-mail: careyr@cnyrc.org

subtype in that many compensatory changes in 5-HT neurons and other transmitter systems occur which make it difficult to connect any of the observed behavioral changes to the absence of the receptor subtype vs the compensatory changes to this missing receptor subtype. Furthermore, this type of genetic subtraction manipulation affects the expression of the 5-HT receptors throughout the brain. In order to assess 5-HT involvement in complex behavioral effects, it is necessary to selectively manipulate 5-HT neurons which project to the forebrain – namely, the dorsal and median raphe nuclei. Indeed, there have been vast numbers of studies conducted in which dorsal and median raphe nuclei have been damaged by various methods, including electrolytic- and neurotoxin-induced lesions. In view of the relatively inaccessible location and the elongated topography of the raphe nuclei, it is difficult to produce virtually complete lesions of these nuclei using non-specific lesion techniques such as electrolytic and radio-frequency lesion procedures without also damaging surrounding reticular formation and other neuronal tissue. Even more selective lesion methods involving intracerebral injections of neurotoxins such as 5,7-dihydroxy tryptamine infusions (5,7-DHT) can produce asymmetric and incomplete lesions of 5-HT neurons, and can also include non-5HT neuronal damage. In other neurotransmitter systems in which there is an extensive axonal collateralization (e.g., dopamine), it is well documented that neuronal cell loss in the rat must be severe (i.e.,  $\geq 90$  percent; Fornaguera *et al.*, 1994) to produce persistent behavioral deficits. Additionally, it is well-known that in the case of human degenerative diseases such as Parkinson's disease (dopamine neurons) and amyotrophic lateral sclerosis (ALS) (ventral horn motor neurons) that observable behavior deficits tend to occur when cell losses are in the order of 60–80 percent (Agid *et al.*, 1990; Nirmalanathan and Greensmith, 2005). The difficult requirement to produce severe cell loss restricted exclusively to dorsal and median raphe nuclei has diminished the utility of lesion methods; in addition, there is no human neurodegenerative disorder which is specifically linked to the dorsal and median raphe serotonin neurons and that has a specific neurological deficit profile.

Coupled to the intrinsic experimental difficulties of creating an animal model preparation in which the dorsal and median raphe nuclei are selectively destroyed is the related problem of development of appropriate behavioral methods to detect and measure the effects of such manipulations. In rodent models of learning and memory, it is critical to differentiate between learning and performance variables. For example, in a reward-based learning task, a manipulation which alters the reward value of a reinforcement would clearly have a performance effect in that the capacity to acquire the behavioral response may

be intact but the incentive to perform would be changed. Consequently, if an experimental treatment alters the reinforcement value of a stimulus used to motivate learning, then retardation in the acquisition of the learned behavior may occur. Unless a change in the reward value of the motivational stimulus is identified, a deficit in a reward learning task could be mislabeled as a learning/memory deficit. There are also widely used aversive learning tasks in which painful stimuli such as footshock are used to motivate learning. The most commonly used tasks include both passive avoidance tasks, in which the behavior learned is response inhibition of spontaneous behavior that leads to footshock, and, conversely, active avoidance tasks, in which the learned behavior is the acquisition of an active response to avoid a footshock. Clearly, 5HT manipulations that alter sensitivity to the aversive stimulus and/or response output impact upon such learning tests. A reduction in response output would facilitate passive avoidance learning but impair active avoidance; and a 5HT manipulation that increases response output would have the opposite effect. A modification in reactivity to the aversive stimulus used to motivate behavior could enhance/impair learning in both types of tasks. Again, effects upon the motivational properties of the reward/aversive stimulus used in a learning task would be performance effects, rather than effects upon associative capacity. Needless to say, profound effects upon response output are obvious; however, if a serotonergic manipulation leaves an animal seemingly intact motorically, then subtle changes such as the tendency, rather than the capacity, to respond are more difficult to detect. What is needed is a simple measure of the spontaneous baseline activity level of an animal. In fact, a wide variety of behavioral measurement methods have been developed in an effort to make the basic assessment of baseline response output. One of the most widely used methods in rodents is to place a test animal in an open arena and record movement during a fixed time interval. While automated systems incorporating photobeam interruptions have been widely used, this procedure provides only an indirect measure and does not capture the full range of behavioral movement (e.g., rearing, grooming, locomotion). Direct observations in scoring of responses combined with videotape scoring, while labor intensive, can provide a reliable and comprehensive capture of behavioral activity. Detailed behavioral recording is necessary but, nonetheless, is not sufficient in that many environmental variables need to be considered (e.g., arena size, lighting, and test duration and frequency). Lighting conditions are important factors in that white light in rodents is aversive, so that a 5-HT manipulation could impact upon activity indirectly by diminishing or enhancing the aversive quality of the white light. While the diurnal cycle is a

substantial variable affecting rodent activity, for acute testing of activity level dark or red light conditions favor behavioral activation, and therefore may provide less problematic testing conditions for rodents (Nasello *et al.*, 1998). Besides behavioral recording methods and lighting, it is necessary to consider the testing protocol as well.

A major determinant of behavioral activity in a test arena is the novelty/familiarity of the test environment (Cerbone and Sadile, 1994). The greater the novelty of the environment, the greater the behavioral activity in the control treatment groups. Typically, treatment manipulations designed to modify brain serotonin do not use a novel environment to test change in response output. A consideration relevant to the use of a novel environment is that the control group activity level is high, so it becomes more difficult to detect an increase in activity. In several studies, however, with stimulant drugs (i.e., cocaine), we have shown that cocaine at a modest dose level that does not induce behavioral abnormalities or stereotypes increases locomotor activity in a novel environment (Carey and Damianopoulos, 2006). This result indicates that initial activity in a novel environment does not create a response-output ceiling effect, and could be an effective technique to assess 5-HT manipulations on behavioral activation capacity. On the other hand, changes in overall motility can be misleading in that activity changes can occur within a test session (i.e., habituation). 5-HT treatments can modulate locomotor activation in all these forms of expression. In intact control animals, locomotor activation is highest in the initial phase of testing in a novel environment but then progressively declines as the animal acquires familiarity with the test environment. A 5-HT manipulation, therefore, could increase locomotor activation by interfering with the capacity to adapt and acquire familiarity with the test environment. Thus, an overall increase in activity level by itself is not a sufficient assessment of response-output effects of treatment variables, since it may indicate an inability to acquire information about the environment rather than an overactive response system. In order to avoid this possibility, another approach is to place the animal in a test environment for a substantial time period prior to performing a manipulation upon the 5-HT system. In that the pre-exposure lowers the response output of the control treatment to a stable level of response output, this protocol can be seen as an effective way to detect a change in response output. An increase in behavioral activity in such a testing protocol, however, does not necessarily imply direct activation of response systems, in that the increase could also be attributed to an effect of the 5-HT manipulation upon the acquired habituation/familiarity to the test environment so that the environment now becomes more novel and in this way evokes an increase in response output. Thus,

the increase in response output could be a direct motoric effect or it could be indirect by virtue of an impact on stimulus processing or on memory due to a change in context familiarity/habituation. Altogether, these considerations indicate that the seemingly simple measurement of response output can be a daunting task. Alternatively, important information regarding the involvement of the serotonergic system in sensory–motor function has been obtained in studies that have monitored 5-HT activity during the sleep–wakefulness cycle and in response to well-defined stimuli.

### Serotonin and motoric function

The most critical source of information about the between activity in serotonergic neurons and motor function has been provided by studies involving serotonergic hyper- and hypoactivity. A number of investigations have shown that pharmacological over-stimulation of serotonergic system can generate a hypermotility syndrome (Jacobs, 1976) and, in addition, reverse neuroleptic induced hypomotility (Carey *et al.*, 2000). In that excessive serotonergic activity generates a behavioral state of over-activation, the expectation would be that inactivation of serotonin would be linked to behavioral inactivation. Given the difficulty of severely reducing 5-HT activity alluded to earlier, the support for serotonergic inactivity being linked to motoric inactivation has been provided by an unusual source. Studies using unit activity recordings (Trulson and Jacobs, 1979; Jacobs *et al.*, 1981; Trulson and Trulson, 1982) in the serotonergic neurons during the sleep–wakefulness cycle revealed a positive correlation between serotonergic activity and wakefulness. A surprising and startling observation provided by this research was the finding that serotonergic unit activity became essentially silent during rapid eye movement sleep (REM). This is of central importance with regard to the role of serotonin in motoric function in that during REM sleep, when there is intense brain activity there is a movement paralysis (Stock, 1982; Lai and Siegel, 1988). This naturalistic observational research uncovered a vital function of serotonin in permitting REM sleep without the hazard of sleep-walking/running. In addition, these and other findings indicate that serotonergic activity appears to be critical for movement (Harris-Warrick and Cohen 1982; Jacobs *et al.*, 2000). Although 5-HT activity may be necessary for movement, other sources of evidence have shown that serotonergic activity, by itself, is insufficient to activate lower motor neuron activity (Myslinsky and Anderson, 1978; Takahashi and Berger, 1990). This necessary but not sufficient role for a neurotransmitter is certainly not unique to serotonin, but rather

has pointed-up the critical contribution of serotonin as an enabler of movement through interaction with other neurotransmitter systems (McCall and Aghajanian, 1979; White and Neuman, 1980). A number of investigations have identified the importance of the interaction between the excitatory amino acid (glutamate) and serotonin in the modulation of lower motor neuron activity (Singer *et al.*, 1996; Kodama *et al.*, 1998; Datta *et al.*, 2003). Importantly, this serotonin–glutamate linkage points to new directions in the understanding and possible treatment of the devastating motor neuron disease of amyotrophic lateral sclerosis (ALS) (Steinke and Tyler, 1964; Bertel *et al.*, 1991; Sandyk, 2006).

### Serotonin and sensory input interactions

While the critical contribution of serotonin neurons to movement in the ‘final common motoric neuron pathway’ is well established, the contribution and interaction of serotonergic neurons to higher brain function and to more global activity processes labeled as behavior, needless to say, are less evident. A vast literature has been developed involving a variety of pharmacological, genetic knockouts and lesion manipulations. As mentioned in the initial comments of this chapter, independent variables (i.e., lesions) and dependent variables (i.e., measures of behavior) used in these studies raise many questions and issues regarding the extant literature. Some recent reports, however, appear to suggest an important and new way to understand the critical contribution of the serotonergic system to behavior. A key finding is in the reports of Müller *et al.* (2007) and Pum *et al.* (2007, 2008). Analogous to the electrophysiological findings of Jacobs and Fornal (1999), these investigations employed an *in vivo* monitoring of serotonergic activity using microdialysis in sensory cortex to monitor serotonin release in the awake behaving rat. Critically, this *in vivo* recording technique as with electrophysiological unit recordings involved monitoring of 5-HT systems, and therefore did not disrupt normative ongoing 5-HT activity. These microdialysis investigations showed that drugs (e.g., cocaine) which increase serotonin extracellularly increase serotonin in primary sensory areas of the neocortex, such as the visual cortex. Additionally, these investigations showed that a behaviorally significant visual stimulus (i.e., flashing light) also increased serotonin release in the visual cortex, and this release was accompanied by increased behavioral activation. Importantly, these microdialysis findings have provided a new way to conceptualize the role of serotonin in sensory–motor function by showing that activation of the serotonergic system can directly modulate sensory information at the level of the sensory areas of the neocortex,

and in this way modify the salience or significance of environmental stimuli. Clearly, if the salience of the stimulus is enhanced then the behavioral response will also be amplified. By having a modulatory influence upon direct primary sensory stimuli at the cortical level and on the response output systems, serotonin is situated to have a pivotal role in reactivity to external environmental stimuli by modulation of sensory information in sensory cortices as well as efferent motor neurons in the spinal cord; thereby promoting action, emotion and memory storage.

A study we conducted recently (Carey *et al.*, 2008) is pertinent to the issue of the role of serotonin in processing exteroceptive stimuli and consequent modulation of relevant behavior. We manipulated serotonin availability by the use of low autoreceptor preferring dose levels of the selective 5-HT<sub>1A</sub> agonist (8-OHDPAT) and antagonist (WAY-100635) in a testing paradigm with rats in which we measured the behavioral responsiveness to a small novel object placed at the center of an open field. At dose levels which did not alter overall motility we found that the 5-HT<sub>1A</sub> agonist 8-OHDPAT, at an autoreceptor dose level (0.025 mg/kg), which inhibits activity in serotonin neurons, diminished behavioral responses to the novel object visual stimulus, whereas a selective autoreceptor antagonist, WAY-100635, which can enhance ongoing serotonin activity (Müller *et al.*, 2002), increased responsiveness to the novel object. As the dose level of these drugs was increased to 0.05 mg/kg the effect became exaggerated; and in the case of the agonist 8-OHDPAT it virtually eliminated responsiveness to the novel object as well as motor activity. Consistent with a stimulus salience interpretation, these findings can be related to the motor paralysis during REM sleep when the serotonergic system becomes inactive. That is, the absence of serotonergic activity during REM sleep would not only impede activity in lower motor neurons, but seemingly would also blunt the influence of external stimuli by severely diminishing their salience and in this way complement the movement paralysis to allow the intense internal brain activity of REM sleep.

### Serotonin and sensory–motor reactivity

On a less dramatic level in the sleep–wakefulness cycle it can be argued that modest changes in serotonergic activity can alter behavioral reactivity to stimuli and response readiness. This conceptualization of the role of serotonin fits well with a framework implicating decreased 5-HT activation in behavioral disorders such as depression. Seemingly, reduced 5-HT activity would contribute to a diminished interest in external environmental stimuli and events by not providing the critical amplification of stimulus salience necessary for eliciting effective and

appropriate responses. Alternatively, a hyperactivity of the 5-HT system may contribute to hypomania and drug-seeking activity by exaggeration of the salience of reward-related stimuli. Clearly, serotonergic systems have a vital modulatory role in sensory–motor function, and the use of exploratory behavior elicited by stimulus salience variation is a new and important direction for understanding the contribution of the serotonergic brain systems in cognition and behavior. Overall, the anatomy of the serotonergic system provides the basis for the critical role of the serotonergic systems in sensory–motor function. In the primary sensory neocortex the serotonergic neurons have dense arborization (Azmitia and Segal, 1978); similarly, in the final common path at the level of the  $\alpha$ -motor neurons, the serotonergic arborization is also dense (Takeuchi *et al.*, 1983; Doly *et al.*, 2004). Thus, at two key loci for the control of behavior – one for the stimulus (sensory cortices) and one for the response ( $\alpha$ -motor neurons) – the serotonin projections are anatomically positioned to profoundly modulate behavior.

# Role of the Serotonergic System in Appetite and Ingestion Control

Michelle D. Lee<sup>1</sup> and Peter G. Clifton<sup>\*,2</sup>

<sup>1</sup>*Department of Psychology, Swansea University, Swansea, UK*

<sup>2</sup>*Department of Psychology, University of Sussex, Brighton, UK*

**Abstract:** Three decades on from Blundell's suggestion that serotonin serves to orchestrate endogenous satiety, we present an overview of the behavioral, pharmacological and neurological evidence that underpins our understanding of the role of serotonin in the control of appetite. Early human and rodent studies, many using fenfluramine, provided initial support for the hypothesis. The more recent characterization of serotonin receptor subtypes, the development of selective pharmacological probes, and the use of transgenic mice unable to express certain 5-HT receptor subtypes has identified specific roles for the 5-HT<sub>2C</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>6</sub> receptor subtypes in feeding behavior. It has also provided support for the development of 5-HT<sub>2C</sub> receptor agonists as a treatment for obesity. Serotonin acts at multiple brain sites to enhance satiety; these include the nucleus of the solitary tract and lateral parabrachial nucleus in the brainstem and hypothalamic sub-regions such as the arcuate and paraventricular nuclei. There are important interactions between serotonin- and hypothalamic peptide-containing cells, especially those expressing  $\alpha$ -melanocyte stimulating hormone and Neuropeptide Y. Serotonin also has important interactions with cholecystokinin at the brainstem level. The multiplicity of these interactions has been reflected in the realization that serotonin has multiple influences at the behavioral level, which range from the mediation of short-term satiation in response to gastric distension and the presence of gut nutrients, to modulation of the responses evoked by conditioned cues that lead to the initiation of feeding.

**Keywords:** serotonin, satiety, appetite, 5-HT, 5-HT<sub>2C</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>6</sub>, obesity, feeding, body weight, fenfluramine

**Abbreviations:**  $\alpha$ MSH,  $\alpha$ -melanocyte stimulating hormone; 5-HTP, 5-hydroxy-L-tryptophan; 8-OH DPAT, 8-hydroxy-2-di-n-propylamino-tetralin; AGRP, Agouti-related peptide; CCK, cholecystokinin; GABA, gamma-amino butyric acid; KO, knockout; LH, lateral hypothalamus; MC, melanocortin; mCPP, m-chlorophenylpiperazine; NPY, Neuropeptide Y; NTS, nucleus of the solitary tract; PBN, parabrachial nucleus of the pons; POMC, pro-opiomelanocortin; pCPA, para-chlorophenylalanine; TFMP, N-[3-trifluoromethyl]piperazine

## Introduction

Evidence for the involvement of serotonin in the neurobiology of appetite first began to accumulate in the early 1970s. Amongst the factors that stimulated these early studies were an interest in the role of the hypothalamic neurotransmitter systems in the regulation of feeding and drinking (Grossmann, 1960), and the discovery of fenfluramine, a non-stimulatory derivative of amphetamine (van Rossum and Simons, 1969) that quickly replaced amphetamine itself in the clinical treatment of obesity. Samanin's group was the first to report that lesions of

the raphe nucleus attenuated the hypohagic effect of fenfluramine but had no effect on reductions of food intake induced by amphetamine (Samanin *et al.*, 1972) and, shortly afterwards, showed that depletion of central dopamine, using intraventricular 6-hydroxydopamine with pargyline pretreatment, attenuated the hypohagic effects of amphetamine and several other psychostimulants (Samanin *et al.*, 1975). The clear implication was that fenfluramine-induced hypophagia depended on enhanced brain serotonergic activity whereas amphetamine probably achieved its effect through a dopaminergic mechanism. However, Samanin did not suggest, at this point, that serotonin might play a role in the endogenous modulation of feeding behavior. Early studies by Blundell demonstrated further dissociations in the effects of fenfluramine

\*Corresponding author  
E-mail: pete@sussex.ac.uk

and amphetamine. The hypophagic effect of amphetamine was reduced in rats with lateral hypothalamic (LH) lesions, whereas the effect of fenfluramine was enhanced (Blundell and Leshem, 1974). An early microstructural study demonstrated that fenfluramine reduced meal size whereas amphetamine increased intermeal intervals (Blundell *et al.*, 1976). In addition, para-chlorophenylalanine (*p*CPA), which depletes serotonin, was shown to increase food intake and result in obesity (Breisch *et al.*, 1976). Blundell's seminal review (Blundell, 1977), which became a citation classic, synthesized these early studies and proposed that endogenous serotonin inhibits food consumption by augmenting short-term satiety processes both during a meal, and the subsequent post-ingestive period.

### Serotonin and feeding behavior: early studies with human participants

Much of our understanding of the role of the serotonergic system in the control of appetite and ingestive behavior has developed from studies carried out in the 1980s and early 1990s using the serotonin releaser and reuptake inhibitor fenfluramine (Garattini *et al.*, 1986, 1987), initially as the racemic dl-fenfluramine and later the more potent isomer d-fenfluramine. In fact, until 1997, when fenfluramine was withdrawn as an anti-obesity treatment due to its association with valvular heart disease (Connolly *et al.*, 1997), it was the prototypical compound for investigating serotonergic mechanisms underpinning food intake and satiety.

Goodhall and Silverstone characterized both the behavioral and pharmacological profile of fenfluramine-induced anorexia in a series of studies in lean human volunteers (Goodall and Silverstone, 1988a,b; McGuirk *et al.*, 1991; Goodall *et al.*, 1992, 1993). In all of the studies participants were allowed to choose an *ad libitum* lunch through the use of an adapted self-service food dispenser that recorded both the timing and choice of single food items. These food items were varied to give a choice of macronutrients and also both sweet and non-sweet foods. The food types that were offered, such as a chicken sandwich or a portion of crackers and cheese, were high in the proportion of energy derived from either carbohydrate or fat, whereas protein content was kept relatively stable. The initial studies (Goodall and Silverstone, 1988a,b) indicated that the d-fenfluramine reduced subjective ratings of hunger as well as intake of non-sweet carbohydrates and fat, but spared protein intake. Furthermore, administration of the non-selective 5-HT<sub>1/2</sub> receptor antagonist metergoline partially reversed the reduction in non-sweet food caused by d-fenfluramine. Similar effects of d-fenfluramine have been shown in an obese population (Wurtman *et al.*, 1985).

In a more detailed microstructural analysis in humans, McGuirk *et al.* (1991) found that d-fenfluramine decreased the rate of eating without altering the duration of the meal. This pattern of eating was distinct from that of d-amphetamine, which reduced intake by shortening meal duration, but did not affect the rate of eating. This finding was consistent with an earlier report by Rogers and Blundell (1979), where dl-fenfluramine slowed within-meal rate of eating but did not alter latency to initiate eating, unlike d-amphetamine administration, which delayed the start of eating and increased eating rate.

Goodall *et al.* (1993) found that the 5-HT<sub>2A/2C</sub> receptor antagonist ritanserin blocked the preferential anorexiogenic action of d-fenfluramine on cumulative fat intake during a self-service lunch. Moreover, ritanserin alone did not increase food intake compared to placebo, consistent with a true antagonist effect. Interestingly, the effect of d-fenfluramine on cumulative fat intake became more pronounced as the meal progressed, suggesting a drug-induced enhancement of satiation during the meal.

The findings of Silverstone and colleagues were significant in establishing the pharmacological profile of d-fenfluramine-induced hypophagia in humans, as well as demonstrating the importance of behavioral measures of food intake. Their data also suggested that the inhibitory effect of d-fenfluramine on food consumption was mediated by 5-HT<sub>1</sub> and/or 5-HT<sub>2</sub> receptor subtypes. This was consistent with contemporary data obtained from studies using rats; Neill and Cooper (1989) utilized the most selective pharmacological tools available at the time in an attempt to elucidate the receptor subtypes through which d-fenfluramine exerted its anorexigenic effect. The effect of d-fenfluramine was reversed by the 5-HT<sub>2A/2C</sub> antagonist ritanserin and the 5-HT<sub>1A/1B</sub> antagonist cyano-pindolol, as well as the non-selective 5-HT<sub>1</sub> antagonist metergoline, but not by the peripheral antagonist xylamide, or by the 5-HT<sub>2</sub> antagonists ketanserin and ICI 169 369 (both with low affinity for 5-HT<sub>2C</sub> receptors).

It was widely assumed that rather than directly stimulating postsynaptic receptors, d-fenfluramine reduced food consumption indirectly by increasing 5-HT availability at these receptors. However, Curzon and colleagues (Gibson *et al.*, 1993; Oluyomi *et al.*, 1994; Curzon *et al.*, 1997) demonstrated, in rats, that d-fenfluramine was still able to reduce food intake after a dose of *p*CPA that significantly depleted extra-raphe 5-HT levels and blocked the ability of d-fenfluramine to increase 5-HT transmission in medial hypothalamic areas. These findings clearly pointed to a direct effect of d-fenfluramine at 5-HT receptors. In addition, Gibson *et al.* (1993) confirmed that the active metabolite d-norfenfluramine stimulated 5-HT<sub>2C</sub> receptors by showing that the anorexiogenic effect of this metabolite, but not the parent compound, was reversed by the 5-HT<sub>2C</sub>

antagonist 1-naphthylpiperazine. As more selective antagonists have become available it has been possible to confirm that the direct and indirect effects of d-fenfluramine on food intake are mediated by 5-HT<sub>2C</sub> receptors (Vickers *et al.*, 2001). Further support has come from studies using transgenic mouse models of 5-HT function where mice lacking functional 5-HT<sub>2C</sub> receptors have been shown to be obese (Tecott *et al.*, 1995), and resistant to d-fenfluramine-induced hypophagia.

Since the withdrawal of d-fenfluramine as an anti-obesity treatment, sibutramine is the only serotonergic anti-obesity drug currently available in the clinic (Heal *et al.*, 1998). Nevertheless, this extensive body of work centered on fenfluramine has served to focus attention on the role of specific 5-HT receptors in the inhibitory control of food intake. What is more, it has provided much of the impetus for the development 5-HT<sub>2C</sub> receptors agonists, such as lorcaserin, as potential anti-obesity agents (Thomsen *et al.*, 2008).

### **Serotonin and satiety: the role of serotonin receptor subtypes**

#### ***5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors and feeding***

Satiation, which is the process that leads to the termination of a meal, is mediated by a cascade of cognitive and pre-ingestive cues. Satiety, a state associated with a greatly lowered probability of feeding, is maintained by post-ingestive cues that have resulted from the digestion and absorption of nutrients gained from previous meals. The initiation of feeding depends on both interoceptive cues that arise from gradually decreasing energy availability, as well as response to incentive-related cues and to more general signals such as time of day. Blundell (1977) explicitly postulated a role for serotonin in satiation and satiety. Since then it has become clear that serotonin and its receptors may modulate both the termination of a meal, and the initiation of the next meal, through actions at multiple sites within the nervous system. These actions are likely to be triggered as a consequence of effects on gut functioning, the processing of both interoceptive and exteroceptive stimuli relevant to ingestion, as well as effects on motivational systems. Subsequently, Simansky (1996) presented a robust argument in favor of a pivotal role for serotonin in regulating satiety that was reinforced by pharmacological evidence. The case for serotonin as a CNS satiety factor was based on accumulating evidence from rodent studies using techniques that afforded a detailed analysis of the organization of feeding responses both within and between meals and over longer time periods. Two such microstructural paradigms that have

been particularly useful in determining the contribution of serotonergic mechanisms to ingestive behavior are the behavioral satiety sequence and meal-pattern analysis in free-feeding rodents and humans.

The behavioral satiety sequence (for an extensive review see Halford *et al.*, 1998) describes a repertoire of behaviors in rodents that occur in an orderly progression during a feeding episode of between 30 and 60 minutes. When food is first presented, feeding (manipulating or chewing food) immediately becomes the dominant behavior, which then gradually gives way to a period of activity (rearing, sniffing, locomotion) followed by grooming, rest and sleep. The satiety sequence is absent during sham feeding (Young *et al.*, 1974), but is advanced in time with a more rapid transition to rest, by pre-feeding a small amount of food prior to the test meal (Cooper and Francis, 1993; Kitchener and Dourish, 1994). The critical measure of augmentation of satiety processes, therefore, is that a compound or manipulation should reduce food intake and hasten the transition through the sequence, whilst keeping the overall pattern of behavior intact. Perhaps the original example of the application of the satiety sequence is the pioneering work of Smith and Gibbs, who first described the gastrointestinal peptide cholecystokinin (CCK) as a satiety factor on the basis that it curtailed sham feeding and elicited the complete satiety sequence (Antin *et al.*, 1975).

Microstructural analyses of meal patterns (for review see Clifton, 2000) typically involve apparatus that allows each rat to access 45-mg food pellets from a food magazine in such a way that each pellet removed can be time-logged precisely. To ensure an accurate record of intake the cage environment must be adjusted to prevent hoarding, so that each pellet is eaten before another can be taken. In addition, water intake is monitored in fine detail by logging each tongue contact with a drinking spout and delivering water through activation of a pump. In general, rodents can be housed in this meal-pattern apparatus for several weeks at a time, allowing for continuous records of feeding and drinking responses to be collected before, during and after drug treatment. Consequently, analysis of feeding records can provide measures of latency to feed, meal size and duration, meal frequency, and rate of eating, with similar data for drinking records. From these various inter-meal and intra-meal parameters, it is possible to tease out any satiety-enhancing consequences of an experimental manipulation. Thus, a decrease in meal size without a delay in beginning the meal is a behavioral correlate of within-meal satiation (the process which terminates a meal), whilst an increase in inter-meal interval suggests enhanced post-ingestive satiety. Simansky (1996) suggested that drug-induced alterations of feeding rate require careful interpretation, as slowing of feeding

rate could indicate non-specific motor effects. However, there is evidence, in both humans (Rogers and Blundell, 1979) and rats (Clifton, 2000), demonstrating that the rate of eating decreases towards the end of a meal as satiation becomes advanced.

These techniques have been applied to studies of drugs that stimulate serotonin availability, direct 5-HT agonists, selective 5-HT receptor antagonists, and 5-HT receptor knockout mice, leading to a clear consensus that much of the inhibitory effect of serotonergic agents on food consumption arises through the potentiation of endogenous satiety. Confirmation of earlier work (Blundell *et al.*, 1976) suggesting that fenfluramine potentiated satiety processes was provided by Burton *et al.* (1981), who showed that fenfluramine reduced meal size in a dose-dependent manner, whilst meal duration and inter-meal interval were unchanged. These early findings were expanded by meal-patterning studies using the serotonin precursor 5-hydroxy-L-tryptophan (5-HTP) (Fletcher, 1986) and the serotonin reuptake inhibitors fluoxetine (Clifton, 1989; Lee and Clifton, 1992) and sertraline (Simansky and Vaidya, 1990). These studies confirmed a fenfluramine-like reduction in meal size and rate of eating without any alteration of meal frequency when serotonin levels were raised by compounds structurally distinct from fenfluramine.

Meal-pattern analyses of a range of 5-HT agonists lend support to the view that serotonin serves to inhibit ingestion by modulating satiety, and have also provided a more accurate picture of the role of specific subtypes of 5-HT receptors. The 5-HT<sub>1B/2C</sub> agonist mCPP has been shown to decrease meal size and rate of eating (Simansky and Vaidya, 1990; Clifton *et al.*, 1993), but also had marked effects on water intake (Clifton *et al.*, 1993). These studies pinpointed a role for 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors in controlling meal-related satiety consistent with Vickers and colleagues (Vickers *et al.*, 2001), who reversed the hypophagic effect of d-fenfluramine with the selective 5-HT<sub>2C</sub> antagonist SB-242084 but not the 5-HT<sub>1B/1D</sub> antagonist GR-127935 or the 5-HT<sub>1B</sub> antagonist SB-224289. The preferential 5-HT<sub>2C</sub> agonist Ro 60-0175 also proved a useful probe of the role of this receptor in ingestive behavior. Clifton *et al.* (2000) compared Ro 60-0175 and d-fenfluramine in a meal-pattern experiment. Ro 60-0175 and d-fenfluramine reduced meal size, without changing meal frequency. However, d-fenfluramine but not Ro 60-0175, except at the highest dose, slowed the rate of eating. Moreover, the selective effect of the agonist on meal size was completely reversed by the 5-HT<sub>2C</sub> antagonist SB-242084. The 5-HT<sub>2C</sub> antagonist also reversed the decrease in feeding rate caused by d-fenfluramine, strongly supporting a role for 5-HT<sub>2C</sub> receptors in the control of eating rate despite

the lack of effect of Ro 60-0175 on this parameter. Together these findings suggested that stimulation of role 5-HT<sub>2C</sub> receptors selectively inhibits food consumption by augmenting within-meal satiation.

Meal-pattern analyses of compounds acting at 5-HT<sub>1B</sub> receptors have shown that there are subtle differences in the behavioral profile of drugs that act at 5-HT<sub>1B</sub> receptors compared to 5-HT<sub>2C</sub> receptors. Early investigations of the role of 5-HT<sub>1B</sub> receptors in ingestion control depended on the administration of RU 24969, which has high affinity for both 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors. However, the decrease in feeding seemed to be attributable to 5-HT<sub>1B</sub> receptors, as the selective 5-HT<sub>1B</sub> receptor antagonists cyanopindolol and pindolol attenuated RU 24949-induced hypophagia (Kennett *et al.*, 1987; Kennett and Curzon, 1988). Most accounts of the affect of RU 24969 on feeding only provide short-term intake data rather than meal patterns, but Simansky and Vaidya (1990) reported that an ED<sub>50</sub> dose of RU 24969 reduced meal duration, but had no direct affect on the rate of eating. The selective 5-HT<sub>1B</sub> agonist CP-94,253 (Koe *et al.*, 1992) proved a more reliable probe of 5-HT<sub>1B</sub> receptor function in ingestive behavior. A meal-pattern analysis using CP-94,253 was conducted by Lee *et al.* (2002), demonstrating a dose-related reduction in meal size and duration without any concomitant slowing of the rate of eating, consistent with the profile of RU 24969 (Simansky and Vaidya, 1990). However, the authors also measured the pattern of water consumption and found that CP-94,253-treatment caused a significant hypodipsia which outlasted the effect of this agent on food intake – an effect which had not previously been seen after 5-HT<sub>2C</sub> agonist administration (Clifton *et al.*, 2000). Lee *et al.* (2002) concluded that it was likely that 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptor subtypes controlled separate elements of satiety, with 5-HT<sub>1B</sub> receptors responsible for meal size and 5-HT<sub>2C</sub> receptors regulating rate of eating. This conclusion was consistent with the findings of Grignaschi and Samanin (1992), who demonstrated that the meal-size effect of d-fenfluramine was blocked by pretreatment with the 5-HT<sub>1A/1B</sub> antagonist (±)-cyanopindolol, whereas the effect on feeding rate was blocked by the 5-HT<sub>2A/2C</sub> antagonist ritanserin. The action of d-fenfluramine on both meal size and rate of eating was blocked by the 5-HT<sub>1/2</sub> antagonist metergoline (Grignaschi and Samanin, 1992). Further evidence that recruitment of both receptor subtypes is necessary for a complete effect on satiety came from meal pattern analyses of the 5-HT<sub>1B/2C</sub> agonist mCPP, which decreased meal size *and* reduced feeding rate (Simansky and Vaidya, 1990; Clifton *et al.*, 1993).

The consensus view that the effects of 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors on satiety process can be dissociated has been reinforced by findings from studies employing the

behavioral satiety sequence. These findings are, in general, consistent across several laboratories utilizing a range of test meals (palatable wet mash, standard rodent chow, sweet solutions) and recording methods (time-sampled observations, analysis of video-tape, and continuous recording) in both rats and mice. A number of authors have demonstrated that raising levels of available 5-HT using serotonin reuptake inhibitors leads to a more rapid transition through the behavioral satiety sequence whilst maintaining the structure of the sequence, consistent with a potentiation of satiety (Clifton *et al.*, 1989; Simansky and Vaidya, 1990; McGuirk *et al.*, 1992). Perhaps unsurprisingly, given its more complex mechanism of action, and the use of different isomers, the effect of fenfluramine on the satiety sequence has been more variable. Some early reports in rats suggested that both the racemate and the more potent *d* isomer of fenfluramine inhibited the resting phase of the sequence, and should therefore not be considered to be a satiety-enhancing agent when given acutely (Montgomery and Willner, 1988; Willner *et al.*, 1990), although this was not consistent with earlier work by Blundell and McArthur (1981). For a more detailed discussion of this issue, see Halford *et al.* (1998). More recently, Vickers *et al.* (1999) and Hewitt *et al.* (2002) have demonstrated a selective effect of *d*-fenfluramine in advancing the satiety sequence, including an enhancement of rest, in C57BL/6 mice.

Comparisons of the behavioral profile of a range of selective agonists have proved fruitful in elucidating the contribution of 5-HT receptor subtypes to endogenous satiety. Thus, Kitchener and Dourish found that 5-HT<sub>1B/2C</sub> agonists mCPP and TFMPP elicited the complete satiety sequence advanced in time, whereas the 5-HT<sub>1A/1B</sub> agonist RU 24969 and the 5-HT<sub>2A/2C</sub> agonist DOI disrupted the satiety sequence, both by increasing active behaviors and by retarding the transition into rest (Kitchener and Dourish, 1994). It is likely that the disruption to the satiety sequence caused by RU 24969 is due to its action at 5-HT<sub>1A</sub> receptors, as later studies using the more 5-HT<sub>1B</sub> agonist CP-94,253, which has a 45-fold greater affinity for 5-HT<sub>1B</sub> over 5-HT<sub>1A</sub> receptors (Lee and Simansky, 1997; Lee *et al.*, 2002), showed an early termination of feeding, without disrupting the sequence. Furthermore, resting behavior was increased in the final phase of the sequence when a palatable wet mash was used as the test meal (Lee *et al.*, 2002). This finding is consistent with those of O'Neill and Parameswaran (1997), who found dual stimulation of both 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors was necessary before increases in locomotor activity were noticeable. The characterization of the preferential 5-HT<sub>2C</sub> agonist Ro 60-0175 on indices of satiety consolidated earlier data collected using *d*-fenfluramine (Vickers *et al.*, 1999). Thus, Hewitt and colleagues compared two doses

of Ro 60-0175 against a behaviorally selective dose of *d*-fenfluramine in the mouse, and found that this agonist produced the expected leftwards shift in the sequence of behaviors, and also increased rest at the end of the sequence (Hewitt *et al.*, 2002). Perhaps the most selective 5-HT<sub>2C</sub> agonist characterized so far is VER23779 (Richter *et al.*, 2006). This highly selective compound, consistent with earlier reports of the effects of Ro 60-0175, reduced food intake by enhancing satiety in a behaviorally selective manner (Somerville *et al.*, 2007).

Converging evidence in support of a critical role for 5-HT<sub>2C</sub> receptors in ingestion control has also come from work in receptor knockout mice. More specifically, mice lacking functional 5-HT<sub>2C</sub> receptors eat more and are heavier compared to lean wild-type littermates (Tecott *et al.*, 1995; Heisler *et al.*, 1998), consistent with tonic inhibitory control of intake by serotonergic systems. Vickers *et al.* (1999) analyzed the effect of *d*-fenfluramine on the behavioral satiety sequence in 5-HT<sub>2C</sub> receptor knockout mice and wild-type controls. In wild-type mice consuming a palatable wet mash meal, *d*-fenfluramine reduced food intake and produced a temporally advanced, yet intact, satiety sequence. This satiety-like effect of *d*-fenfluramine was blunted in mice lacking the 5-HT<sub>2C</sub> receptor. A later study (Clifton, 2000) showed that the *d*-fenfluramine-induced reduction in meal size, measured in a mouse meal-pattern paradigm, was absent when 5-HT<sub>2C</sub> knockout mice were treated with the same dose of *d*-fenfluramine.

It has proved more difficult, using mouse genetic models, to further clarify the role of 5-HT<sub>1B</sub> receptors in the serotonergic control of appetite. 5-HT<sub>1B</sub> knockout mice do display a hyperphagic phenotype and increased body weight compared to wild-type mice (Bouwknegt *et al.*, 2001). These animals are also insensitive to the effects of *dl*-fenfluramine both on feeding behavior and on *c-fos* induction in hypothalamic and amygdala sub-regions (Lucas *et al.*, 1998). However, the behavioral data are in striking contrast to those collected using selective 5-HT<sub>1B</sub> antagonists. Lee *et al.* (2004) reported that 5-HT<sub>1B</sub> knockout mice showed reduced sensitivity to the hypophagic and satiety-enhancing profile of *d*-fenfluramine. However, in wild-type mice *d*-fenfluramine-induced anorexia, and changes in the satiety sequence were not reversed by either the 5-HT<sub>1B/1D</sub> antagonist GR-127935 or the selective 5-HT<sub>1B</sub> antagonist SB-224289. Clifton *et al.* (2003) demonstrated that 5-HT<sub>1B</sub> knockout mice were less responsive to an active dose of the 5-HT<sub>2C</sub> receptor agonist Ro 60-0175, which significantly reduced food intake in wild-types. Moreover, the effect of the same dose of Ro 60-0175 was not reversed by the selective 5-HT<sub>1B</sub> antagonist SB224289. The reduced responsiveness to probes of 5-HT<sub>2C</sub> function also generalized to measures

of locomotor activity, and to the induction of *c-fos* immunoreactivity in several brain regions. These findings prompted Clifton *et al.* (2003) to conclude that compensatory changes in 5-HT<sub>2C</sub> receptor function following loss of 5-HT<sub>1B</sub> receptors limited the conclusions that could be drawn from this knockout model in relation to the serotonergic control of feeding.

One potentially important difference between the effects of 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptor activation on ingestive behavior has emerged from the use of modified second-order schedules of reinforcement in mice. In such a schedule, mice are trained to respond for food during 30-minute sessions in which, during the first 5 minutes, responding is maintained by the presentation of a conditioned stimulus associated with food delivery rather than by food itself (Somerville *et al.*, 2007). Since the schedule is relatively lean even after this initial period, food consumption typically starts about 10 minutes into the session. Thus, each test session can be considered as comprising an initial appetitive component followed by a mixed appetitive/consummatory component. The 5-HT<sub>1B</sub> receptor agonist CP94,253 led to similar reductions in responding during both the appetitive and mixed components, whereas the selective 5-HT<sub>2C</sub> receptor agonist VER23779 produced a much greater relative reduction in appetitive responding (Somerville *et al.*, 2007). This result implies that 5-HT<sub>2C</sub> receptor activation may play a particular role in modulating response to conditioned cues associated with food. These behavioral differences were associated with differences in regional induction of *c-fos* immunoreactivity by the two drugs. In particular, VER23779 produced marked activation of the basolateral amygdale, which was absent with CP94,253-treatment.

### 5-HT<sub>1A</sub> receptors and feeding

The 5-HT<sub>1A</sub> receptor has a well-defined inhibitory action in the raphe nucleus as a somatodendritic autoreceptor. There are also important postsynaptic populations of 5-HT<sub>1A</sub> receptors in hippocampal sub-regions. In rodents, the prototypical 5-HT<sub>1A</sub> receptor agonist 8-hydroxy-2-di-n-propylamino-tetralin (8-OH DPAT) has a biphasic action on feeding. Low doses (typically less than 0.5 mg/kg) stimulate food intake, whereas higher doses reduce food intake (Dourish *et al.*, 1985). Food intake is also stimulated when 8-OH-DPAT is directly injected into the median raphe nucleus (Currie and Coscina, 1993), suggesting that this effect arises from inhibition of serotonergic raphe cell firing due to the activation of 5-HT<sub>1A</sub> autoreceptors. Higher doses that reduce feeding are likely to act at postsynaptic 5-HT<sub>1A</sub> receptors, and

their effects are completely reversed by the pretreatment with the 5-HT<sub>1A</sub> receptor antagonist WAY-100635, although the antagonist had no intrinsic action on feeding in the test paradigm (Vickers *et al.*, 1996). Such doses of 8-OH-DPAT induce a characteristic behavioral syndrome (Tricklebank *et al.*, 1984), which may be partly responsible for the reduction in food intake. The enhanced feeding induced by low doses of 8-OH-DPAT is a variable phenomenon. For example, doses that stimulate feeding in sated animals may depress food intake in food-deprived animals (Dourish *et al.*, 1985; Ebenezer, 1992). In addition, a dose of 8-OH-DPAT that stimulates feeding in normal rats has no effect on feeding in older obese Zucker rats, and inhibits feeding in younger obese animals (Voigt *et al.*, 2002). The same shift in the effect of 8-OH-DPAT is observed in rats that have consumed a sugar-rich diet and become obese (Inam *et al.*, 2008). Both studies suggest that as obesity develops, there may be changes in the sensitivity of raphe serotonergic neurons to autoreceptor feedback.

Animals over-expressing the 5-HT<sub>1A</sub> receptor do not show changes in food intake or body-weight regulation (Kusserow *et al.*, 2004). The same is true of 5-HT<sub>1A</sub> receptor null mutant mice (Zhuang *et al.*, 1999). However, Lucki and colleagues have recently demonstrated that female, but not male, 5-HT<sub>1A</sub> receptor knockout mice over-consume a sucrose solution (Bechtholt *et al.*, 2008). There are other indications that 5-HT<sub>1A</sub> receptors may be involved in sex differences in feeding. For example, Currie *et al.* (2004) demonstrated that, although intra-raphe infusion of 8-OH-DPAT could reverse the hypophagic effect of the selective serotonin reuptake inhibitor fluoxetine in male rats, the same treatment was ineffective in female rats unless they had been ovariectomized.

### 5-HT<sub>6</sub> receptors and feeding

The 5-HT<sub>6</sub> receptor was only characterized in the 1990s and, as with the majority of other 5-HT receptor subtypes, is a G protein positively linked to adenylyl cyclase (Barnes and Sharp, 1999). 5-HT<sub>6</sub> receptor mRNA is found at high levels in the striatum and hypothalamus in several mammalian species (Kohen *et al.*, 1996). Rat autoradiographic studies, using the specific 5-HT<sub>6</sub> radioligand, [<sup>125</sup>I]-SB-258585, demonstrated a high density of binding in discrete hypothalamic nuclei, including the arcuate, lateral, anterior and dorsomedial hypothalamus (East *et al.*, 2002).

The first significant indication that 5-HT<sub>6</sub> receptors might play an important role in feeding and body-weight regulation came from a study in which the primary focus was on cognitive performance. Woolley and colleagues

used two techniques to reduce 5-HT<sub>6</sub> receptor function. These were intracerebroventricular (ICV) administration of an antisense oligonucleotide that was complementary to the gene for the rat 5-HT<sub>6</sub> receptor, and chronic systemic administration of the putative 5-HT<sub>6</sub> receptor antagonist Ro 04-6790 (Woolley *et al.*, 2001). In addition to enhancing retention for spatial position in the Morris water maze, both manipulations reduced food intake and body weight. These findings are complemented by studies of 5-HT<sub>6</sub> gene manipulations in mice. Null mutation of the 5-HT<sub>6</sub> receptor gene had no effect on food intake and body weight when mice were fed a normal diet. However, when these animals were given access to a high fat diet over an 11-week period, food intake was reduced by 8 percent and body weight decreased by 35 percent relative to wild-type controls (Frassetto *et al.*, 2008). As these data suggest, the relatively large reduction did not solely depend on lower food intake, but was amplified by a reduction in the efficiency with which food was transformed into body mass. Data obtained using more potent 5-HT<sub>6</sub> antagonists, such as E-6837, have confirmed that chronic treatment will reduce food intake and body weight (Fisas *et al.*, 2006), but more detailed behavioral analyses are not yet available. Heal *et al.* (2008) have reviewed the clinical implications of these data in detail.

### ***Other 5-HT receptor subtypes and feeding***

Although at least 14 different serotonin receptor subtypes have been identified (Barnes and Sharp, 1999), there is a relative lack of evidence to suggest specific or selective involvement of 5-HT<sub>2A</sub>, 5-HT<sub>2B</sub>, 5-HT<sub>4</sub>, 5-HT<sub>5</sub> and 5-HT<sub>7</sub> receptors in feeding (Clifton and Kennett, 2006), and they are not discussed further here. There is also relatively little evidence to suggest an *independent* role for the ligand-gated, ionotropic 5-HT<sub>3</sub> receptor in feeding, although there are important interactions between this receptor and CCK in mediating effects on feeding behavior; the relevant data are discussed below.

### **Neural mechanisms underpinning serotonergic modulation of feeding behavior**

Taste-responsive neurons project initially to rostral areas of the nucleus of the solitary tract (NTS) (Norgren *et al.*, 2006). The onward projection is to the parabrachial nucleus of the pons (PBN), and then via two routes to the forebrain. One component projects to the thalamus and thence to gustatory cortex; the second projects to limbic areas, including the central gray, amygdala, hypothalamus and bed nucleus of the stria terminalis. This latter

pathway is also likely to be carrying non-gustatory information. Visceral information relating to, for example, gastric stretch also projects to the nucleus of the solitary tract, parabrachial nucleus and then on to these limbic structures.

Brainstem central pattern generators are responsible for the patterning of chewing and other components of ingestive behavior (Lund and Kolta, 2006). They may be directly activated by taste and other stimuli associated with food. Such responses remain intact in the absence of forebrain inputs, and are likely to result from direct excitation by sensory cells within the nucleus of the solitary tract and other brainstem areas. These motor responses are also likely to be under tonic inhibitory control by the basal ganglia, and specifically from GABAergic outputs of the pallidum (Grillner *et al.*, 2005). It is likely that hypothalamic influences on feeding behavior are expressed both through this mechanism and also by more direct connections from the lateral hypothalamus to the brainstem (Goto *et al.*, 2005). The motor components of ingestive behavior are also under additional forebrain control from the cortical masticatory area (Lund and Kolta, 2006).

Serotonin agonists might reduce food intake through their action at several sites, given the widespread distribution of serotonergic neurons and serotonin receptors (Palacios *et al.*, 1990; Törk, 1990) in the nervous system. There is direct evidence to suggest an effect in the brainstem. d-Fenfluramine reduces food intake when infused into the fourth ventricle (Grill *et al.*, 1997). The 5-HT<sub>2C/1B</sub> receptor agonist mCPP also reduces short-term feeding responses when infused into the fourth ventricle (Kaplan *et al.*, 1998). In both cases, the response is seen in neurally intact rats and is also observed in rats in which the neural connections from brainstem to forebrain have been disrupted by a supracollicular section. Such animals have to be maintained by tube feeding, and their feeding responses can only be monitored by infusing a palatable solution into the mouth via an indwelling cannula. However, the reduction of ingestive responses induced by either d-fenfluramine or mCPP suggests an important role for this caudal brainstem structure. The hypophagic effect of d-fenfluramine infused into the fourth ventricle is partially reversed by systemic administration of the 5-HT<sub>1/2</sub> antagonist metergoline (Grill *et al.*, 1997). More significantly, fourth-ventricle infusions of the 5-HT<sub>2C/2A</sub> antagonist mesulergine can abolish the hypophagic effect of systemically administered mCPP (Kaplan *et al.*, 1998), strongly supporting these authors' contention that caudal brainstem serotonin receptors are both '*necessary and sufficient*' for the effects of mCPP on feeding.

Candidate structures for these effects of mCPP and d-fenfluramine include the NTS and the lateral PBN

(Palacios *et al.*, 1990; Wright *et al.*, 1995). There is evidence to support the involvement of both of these structures in the serotonergic modulation of feeding behavior. Cells in both areas show neural activation, as revealed by activation of immediate early genes such as *c-fos* and *c-jun* by fenfluramine (Li and Rowland, 1996). Selective serotonin agonists also activate both areas, though with some sub-regional differences. The selective 5-HT<sub>1B</sub> receptor agonist CP94,253 produces activation in the NTS, though not in the adjacent dorsal vagal and hypoglossal nuclei (Lee *et al.*, 2004). The selective 5-HT<sub>2C</sub> agonist VER23779, by comparison, produced a more restricted activation in the posterior part of the NTS, at the level of the dorsal motor nucleus of the vagus (Somerville *et al.*, 2007). It has also been reported that a selectively hypophagic dose of mCPP activates a specific population of cells within the NTS (Lam *et al.*, 2009). These cells are tyrosine hydroxylase-containing, and are most likely a population of noradrenergic cells which relay viscerosensitive information from the brain stem to forebrain areas (Sawchenko and Swanson, 1982). Relevant and important targets of this projection are the periventricular and lateral hypothalamic areas, both of which are implicated in the control of feeding.

The lateral parabrachial nucleus of the pons is another plausible brainstem target for the action of serotonin agonists on feeding behavior. The selective 5-HT<sub>1B</sub> receptor agonist CP94,25 produces an especially marked activation of the external lateral and dorsal regions of the lateral PBN, although the effects of the selective 5-HT<sub>2C</sub> receptor agonist VER23799 were much less marked (Somerville *et al.*, 2007). Other studies indicate a functional role for both 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors in this area. Axon-sparing lesions of the lateral PBN markedly attenuated the hypophagic effects of systemically administered d-fenfluramine in one study (Li *et al.*, 1994). In addition, this study showed that the lesion leads to a marked attenuation of d-fenfluramine-induced immediate early gene immunoreactivity in the central nucleus and bed nucleus of the stria terminalis. This is consistent with the suggestion that this pathway may mediate some serotonergically-mediated peripheral effects of the ingestion of food on feeding behavior. It also demonstrates that the neural activation of these areas by d-fenfluramine is unlikely to depend on serotonin receptors in those areas, but is indirect, or transynaptic. However, in a second study (Trifunovic and Reilly, 2001), lesions of the lateral PBN had no effect on d-fenfluramine-induced hypophagia. In this study, lesions of the more medial, gustatory area of the PBN enhanced the reduction of feeding behavior induced by d-fenfluramine. One possibility is that this area may contribute to the hedonic evaluation of foods, and thus to the activation of feeding behavior. It is therefore

interesting that lesions of the LH area also enhance the hypophagic action of dl-fenfluramine (Blundell and Leshem, 1974).

Direct infusion of the 5-HT<sub>1B</sub> receptor agonist CP93,129 into the lateral PBN produces a marked reduction in feeding at a low nanomolar dose (Lee *et al.*, 1998). No effects on drinking, grooming or locomotor activity were observed at this dose. In an earlier analysis of the effects of systemically administered 5-HT<sub>1B</sub> receptor agonist CP94,253, Lee and Simansky (1997) established that the changes in drinking microstructure in rats presented with a palatable sucrose solution resembled those associated with enhanced satiety rather than decreased hedonic impact. This observation was consistent with the advancement of the satiety sequence observed by Halford and Blundell (Halford *et al.*, 1998); however, it is clear that both the lateral PBN and the NTS are involved in other regulatory functions, including sodium intake. In this case, activation of serotonergic neurons in the dorsal raphe that project to the lateral PBN is associated with reductions in the intake of a hypertonic sodium solution (Godino *et al.*, 2007).

The hypothalamus remains the pre-eminent area associated with the control of food intake and body weight. There is a substantial body of evidence to suggest that serotonin functions as a key neurotransmitter component of the hypothalamic feeding network. Leibowitz and co-workers, in an extensive series of experiments reported during the 1980s (reviewed by Leibowitz and Alexander, 1998), demonstrated that medial hypothalamic administration of serotonin could reduce food intake. More detailed behavioral studies indicated that this effect resulted from a decrease in meal size while latency to feed and meal frequency were unaffected. These data were consistent with studies that had examined the effects of systemically administered serotonergic agents, and were interpreted in terms of a role for serotonin in satiation. In addition to these effects on food intake, additional studies showed more selective effects when rats were presented with pure macronutrients. A typical result was that the consumption of carbohydrate, presented as polycose, was reduced, whereas intake of fat (typically lard) or protein (typically casein powder) was unchanged. A number of possible interpretations exist for these data. Liebowitz, following the hypothesis initially outlined by Wurtman *et al.* (1986), suggested that the protein-sparing component of the response to serotonergic agents will lead to relatively high circulating levels of tryptophan, the amino acid precursor for serotonin synthesis. This, in turn, will raise the availability of tryptophan in the brain, and increase serotonin synthesis. The net result will be that a high carbohydrate meal leads to increased serotonergic function that will tend to promote protein consumption at the expense of

carbohydrate – a classic negative feedback system. There is a substantial amount of evidence to support different elements of this hypothesis.

However, there are also some important caveats that should be recognized in relation to the experimental data supporting this hypothesis. The macronutrient sources that are used in diet-selection experiments differ in several respects, in addition to their nutrient composition. These include taste, texture and water content. All of these factors may influence feeding behavior directed towards a particular dietary component. In a detailed exploration of this issue, Lawton and Blundell demonstrated that selective suppression of carbohydrate by prior administration of d-fenfluramine could only be obtained under a restricted set of conditions (Lawton and Blundell, 1992). Selective suppression of carbohydrate intake was only observed when hydrated chow (a semi-liquid wet mash) was pitted against dry polycose powder in a choice test. Non-selective suppression of intake was observed in several other conditions. These data must lead to some reservations regarding the elegant theoretical arguments outlined in the previous paragraph.

### Serotonin and downstream peptidergic mechanisms in the hypothalamus

At least since the mid-1990s, it has been clear that there are important interactions between amine and peptide neurotransmitters in the hypothalamus. The arcuate nucleus plays a crucial role in receiving humoral and other inputs that initiate hypothalamic contributions to feeding. Two distinct populations of cells are involved at this level. The first of these express Pro-opiomelanocortin (POMC), a precursor of  $\alpha$ MSH which, when released at terminal endings in the paraventricular (PVN) or LH, acts at MC<sub>4</sub> receptors, leading to a reduction in feeding behavior (Heisler *et al.*, 2003). Disruption of the genes for either POMC or the MC<sub>4</sub> receptor leads to a severe obesity syndrome in both rodents and humans (Heisler *et al.*, 2003). A second population of cells co-express Neuropeptide Y and the endogenous MC<sub>4</sub> antagonist Agouti-related peptide (AGRP). Animals that over-express AGRP show the expected obesity phenotype (Adan *et al.*, 2003). Although constitutive knockout of the NPY gene has no effect on body weight (Erickson *et al.*, 1996), recent studies have demonstrated that targeted ablation of AGRP-containing cells, manipulated so that they also express a diphtheria toxin receptor, leads to reductions in feeding and body weight (Gropp *et al.*, 2005). This suggests that loss of NPY receptors early in development is subject to a compensatory process that renders them less important in feeding regulation during adult life.

More recently, studies by Heisler and colleagues have provided some very interesting insights into the action of serotonergic drugs that reduce feeding behavior on both 5-HT<sub>2C</sub> and 5-HT<sub>1B</sub> receptors expressed by different cell groups in the hypothalamus. In an initial study (Heisler *et al.*, 2002), they determined a threshold dose for the reduction of feeding by d-fenfluramine in rats. This dose was then used in immunohistochemical studies which identified POMC-containing cells activated by fenfluramine. Finally, in an electrophysiological study, it was shown that fenfluramine could activate these POMC-containing cells. More recent work (Heisler *et al.*, 2006) has identified a specific role for 5-HT<sub>1B</sub> receptor activation. First, it was demonstrated that 5-HT<sub>1B</sub> receptors are localized on AGRP containing neurons in the arcuate nucleus. Subsequent experiments demonstrated that the effects of fenfluramine, and of the selective 5-HT<sub>1B</sub> receptor agonist CP94,253, were blunted in mice that either over-expressed AGRP or had non-functional MC<sub>4</sub> receptors. This led these authors to propose a model in which 5-HT<sub>1B</sub> receptors are expressed by NPY/AGRP-containing neurons which, when activated, hyperpolarize them. This would lead to both a reduction in the release of AGRP and NPY, which would lower the activation of downstream feeding centers in the lateral hypothalamus, and a reduction in the secretion of GABA by collaterals of these same neurons which normally inhibit  $\alpha$ MSH-containing neurons in the arcuate nucleus (Cowley *et al.*, 2001).  $\alpha$ MSH-containing cells express 5-HT<sub>2C</sub> receptors (Heisler *et al.*, 2002). Fenfluramine, either through its indirect releasing effects on serotonin, or from metabolites such as *nor*-fenfluramine (which are themselves 5-HT<sub>2C</sub> receptor agonists), depolarizes these cells and increases their firing rate (Heisler *et al.*, 2002). The resultant increase in release of  $\alpha$ MSH would also be expected to decrease the activation of downstream feeding centers. Lam and colleagues used the selective 5-HT<sub>2C</sub> agonist BVT.X and demonstrated that its anorexigenic action was absent in MC<sub>4</sub> knockout mice, again confirming this receptor as a downstream mediator of the effects of 5-HT<sub>2C</sub> receptor stimulation on feeding (Lam *et al.*, 2008).

### Serotonin–CCK interactions

There are important interactions between serotonin and other neurotransmitter systems involved in the mediation of hunger and satiety. The best-described relationship is between CCK and serotonin. Stallone *et al.* (1989) first demonstrated that the non-selective serotonin receptor antagonist metergoline was able to attenuate the hypophagic effect of CCK. A central site of action seemed likely, since xylamidine, another non-selective antagonist

which is not centrally available after systemic administration, was without effect. Subsequently Poeschla *et al.* (1993) showed a similar effect using the relatively selective 5-HT<sub>2C</sub> receptor antagonist mianserin. By contrast, antagonists at the 5-HT<sub>2A</sub> or 5-HT<sub>3</sub> receptor were ineffective. Asarian (2009) has shown that these effects are very likely to involve hindbrain 5-HT<sub>2C</sub> receptors. First, she demonstrated that the hypophagic effect of CCK is not observed in 5-HT<sub>2C</sub> KO mice. In addition, although the induction of *c-fos* immunoreactivity by CCK was normal in the paraventricular and arcuate nuclei of 5-HT<sub>2C</sub> KO mice, CCK failed to evoke the normal *c-fos* response in the nucleus of the solitary tract of 5-HT<sub>2C</sub> KO mice. One likely account of this interaction would be that the satiating effect of CCK, perhaps acting at peripheral vagal afferents, is dependent on 5-HT<sub>2C</sub> receptors located in the nucleus of the solitary tract.

Other evidence suggests a complementary interaction between CCK and 5-HT neurotransmission in the modulation of feeding. Cooper and colleagues were able to show that reductions in feeding behavior induced by fenfluramine were attenuated by pretreatment with the CCK<sub>A</sub> receptor antagonist devazepide (Cooper *et al.*, 1992). Clifton and Cooper (1992) reported that this effect resulted from a specific reversal in the reduction of meal size that was induced by fenfluramine, such that short-term food intake was restored to normal, whereas the subsequent intermeal interval tended to be longer. This suggested that, while serotonergically mediated intra-meal satiation depended on a CCK<sub>A</sub> mechanism, the maintenance of inter-meal satiety did not depend on CCK neurotransmission.

The 5-HT<sub>3</sub> receptor, unlike any other so far discussed, is a ligand-gated ion channel receptor. Although these receptors are quite widely distributed within the nervous system (Morales *et al.*, 1998), they are found in locations that would permit a role in the regulation of feeding, and especially in satiety responses. For example, they are expressed on vagal afferents and in several hindbrain nuclei. The evidence for any direct involvement in the modulation of feeding is contradictory. Several reports suggest no effect on food intake of normally fed or of food-deprived rats (Sugimoto *et al.*, 1996). The selective 5-HT<sub>3</sub> antagonist ondansetron had paradigm-specific effects in another study (Cooper and Francis, 1993). Intake of a sweetened palatable mash was increased, whereas consumption of a palatable sucrose solution was reduced. In a subsequent study from the same group (van der Hoek and Cooper, 1994), the effects of ondansetron on consumption of sweetened mash were examined in greater detail. On this occasion the treatment led to significant *decreases* in intake, which resulted from a

decrease in the duration of feeding rather than from any decrease in feeding rate. High doses of the 5-HT<sub>3</sub> antagonist mCPBG have been reported to reduce food intake, although it was not possible to demonstrate this effect actually involved activation of 5-HT<sub>3</sub> receptors since it was not reversed by the 5-HT<sub>3</sub> receptor antagonist MDL-72222 (Mazzola-Pomietto *et al.*, 1995).

There is also some evidence to suggest that 5-HT<sub>3</sub> receptors may mediate the acquisition of the aversion that develops to a diet unbalanced in amino acids, since it is attenuated by the 5-HT<sub>3</sub> antagonist tropisetron (Aja *et al.*, 1999). The hypophagic response itself may be mediated by CCK<sub>A</sub> receptors, as the effect of tropisetron is blocked by the CCK<sub>A</sub> receptor antagonist devazepide (Aja *et al.*, 1999). 5-HT<sub>3</sub> receptors may play a particular role in the conditioning process that associates the sensory characteristics of the diet with the consequences of amino acid imbalance (Bellinger *et al.*, 2005). 5-HT<sub>3</sub> receptors, again in combination with CCK<sub>A</sub> receptors, may also modulate satiety responses to fat solutions. In one reported paradigm, food was made available to rats for 6 hours each day and the animals then received a duodenal infusion of a fat solution. This manipulation reduced meal size and increased inter-meal interval. Tropisetron, a 5-HT<sub>3/4</sub> receptor antagonist, normalized the inter-meal interval, but not meal size, whereas combined treatment with tropisetron and devazepide resulted in a normalization of both meal size and intermeal interval (Burton-Freeman *et al.*, 1999).

In a recent group of reports, Hayes and colleagues have considerably extended our understanding of the role of 5-HT<sub>3</sub> receptors in mediating satiety-like responses resulting both from gastric distension and from intestinal nutrient content at the level of the hindbrain. For example, in one study using *c-fos* induction as a measure of neuronal activation, they were able to show that CCK-dependent activation of neurons by gastric distension in the dorsal vagal complex, and especially in the nucleus of the solitary tract, depended on activation of 5-HT<sub>3</sub> receptors (Hayes and Covasa, 2006). Thus, this *c-fos* response was attenuated by the 5-HT<sub>3</sub> receptor antagonist ondansetron. In a related study, they examined the role of 5-HT<sub>3</sub> receptors in mediating the suppression of feeding induced by the presence of lipids in the duodenum. Intralipid (a proprietary stable fat emulsion) was infused into the duodenum and resulted in reduced consumption of either a palatable sucrose solution or of chow; these reductions were attenuated by pretreatment with ondansetron, which, in contrast to tropisetron, is selective to the 5-HT<sub>3</sub> receptors (Savastano *et al.*, 2007). In summary, recent evidence suggests that 5-HT<sub>3</sub> receptors, interacting with CCK, may play an important role in mediating short-term satiation

that results from either gastric distension or the presence of nutrients, especially fat, in the upper intestinal tract.

This section has emphasized the contribution of different serotonin receptor subtypes, especially 5-HT<sub>2C</sub> and 5-HT<sub>1B</sub>, to the modulation of feeding. It has also reviewed the interactions between serotonin and hypothalamic peptides, and between serotonin and CCK. However, it is likely that additional roles will come to wider attention. Two examples will suffice. Asarian (2008), in addition to demonstrating the absence of hypophagia induced by CCK in 5-HT<sub>2C</sub> knockout mice, also showed that these animals were insensitive to the effects of glucagon-like peptide (GLP-1) in reducing feeding behavior. Interactions between serotonin and dopamine have been well studied in relation to unconditioned locomotor activity and the effects of drugs of abuse. However, it is also clear that there may be important dopamine–serotonin interactions in the modulation of feeding. Thus, Fletcher *et al.* (2004) demonstrated that infusion of Ro 60-0175 into the ventral tegmental area (VTA) of the rat not only reduced responding for a drug reward but also reduced responding for food.

### Concluding remarks

The potential utility of serotonergic agents in the treatment of obesity is covered in Chapter 4.11 of this volume. The most advanced candidates at present are 5-HT<sub>2C</sub> receptor agonists, although the 5-HT<sub>6</sub> receptor is also a plausible target. It will of course be crucial for any 5-HT<sub>2C</sub> agonist to be sufficiently selective for 5-HT<sub>2C</sub> over 5-HT<sub>2B</sub> receptors, as the valvulopathies associated with d-fenfluramine are due to expression of 5-HT<sub>2B</sub> receptors in cardiac tissue (Fitzgerald *et al.*, 2000). Activation of 5-HT<sub>1B</sub> receptors is also contraindicated because of the potential association with pulmonary arterial hypertension (Dempsey and MacLean, 2008). Although a number of 5-HT<sub>2C</sub> agonists have been developed and progressed to at least Phase I trials, only lorcaserin (Thomsen *et al.*, 2008) is known to be in large-scale Phase III trials.

In summary, our understanding of the role of serotonin in the regulation of feeding behavior has greatly advanced since the original elaboration of the hypothesis that this neurotransmitter enhances satiation and satiety (Blundell, 1977). It is now clear that serotonin plays a broad role in this regard, through its actions at multiple sites in the nervous system, and by modulating a number of distinct behavioral processes. These range from the mediation of short-term satiation in response to gastric distension and the presence of nutrients in the intestinal tract, to modulation of the responses evoked by conditioned cues that lead to the initiation of a feeding bout.

# Serotonin and Sexual Behavior

Lynda Uphouse\* and Jutatip Guptarak

*Department of Biology, Texas Woman's University, Denton, Texas*

**Abstract:** Serotonin's (5-HT) classical role in regulation of sexual behavior is to inhibit copulation. However, the neurotransmitter exerts a more complex influence on the behavior dependent on the particular aspect of the behavior examined. In this chapter, the historical basis for consideration of 5-HT as a major player in sexual behavior is discussed. Current information about the role of 5-HT in the sexual dysfunction that is associated with the use of selective serotonin reuptake inhibitors is reviewed. Information on specific 5-HT receptor subtypes, though far from complete, implicates 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>3</sub> and 5-HT<sub>7</sub> receptors as potential mediators of 5-HT's influence on sexual behavior. Evidence for the involvement of each of these receptor subtypes is reviewed, and their different effects in males and females examined. Finally, the possible biological significance of serotonin's contribution to sexual behavior is examined.

**Keywords:** lordosis, ejaculation, erection, sexual motivation, serotonin receptors, SSRIs, premature ejaculation, appetitive and consummatory sexual behavior.

**Abbreviations:** 5-CT, 5-carboxyamidotryptamine – non-selective, but 5-HT<sub>7</sub> receptor agonist; 5-HT, serotonin; 5-HTP, 5-hydroxytryptophan; 5,7-DHT, 5,7-dihydroxytryptamine – serotonin neurotoxin; 8-OH-DPAT, 8-hydroxy-2-(di-N-propylamino) tetralin – 5-HT<sub>1A</sub> receptor agonist; AH, anterior hypothalamus; CNS, central nervous system; CGS-12066A, 7-trifluoromethyl-4(4-methyl-1-piperazinyl)-piperolo[1,2a]quinoxaline maleate – 5-HT<sub>1B</sub> receptor agonist; DHT, dihydrotestosterone; DOI, (+/-)-1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane HCl – 5-HT<sub>2A/2C</sub> receptor agonist; DRN, dorsal raphe nucleus; GR 127935, N-[4-methoxy-3-(4-methyl-1-piperazinyl)phenyl]-2'-methyl-4'-(5-methyl-1,2,4-oxadiazol-3-yl)-1-1'-biphenyl-4-carboxamide hydrochloride – 5-HT<sub>1B/1D</sub> receptor antagonist; KOIB, 5-HT<sub>1B</sub> receptor knockout; L/M, lordosis to mount ratio; MBH, mediobasal hypothalamus; mCPP, 1-(m-chlorophenyl) piperazine – non-selective, but 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptor agonist; MDL 100907, (±)-2,3-dimethoxyphenyl-1-[2-(4-piperidine)-methanol] – 5-HT<sub>2A</sub> receptor antagonist; MDMA, 3,4 methylenedioxymethamphetamine, 'ecstasy' – 5-HT depleting agent; mPOA, medial preoptic area; mPOA-AH, medial preoptic area-anterior hypothalamus; nPGi, nucleus paragigantocellularis; MRN, median raphe nucleus; POA, preoptic area; PAG, periaqueductal gray; PCPA, parachlorophenylalanine – tryptophan hydroxylase inhibitor; PVN, paraventricular nucleus of the hypothalamus; RS 102221, 8-[5-(2,4-dimethoxy-5-(4-trifluoromethylphenyl)sulfonamido)phenyl-5-oxopentyl]-1,3,8-triazaspiro[4.5]decane-2,4-dione hydrochloride – 5-HT<sub>2C</sub> receptor antagonist; SB206553, N-3-pyridinyl-3,5-dihydro-5-methyl-benzo(1,2-b:4,5-b')dipyrrole-(2H)carboxamide – 5-HT<sub>2B/2C</sub> receptor antagonist; SB 269970A, 2-(2-(4-methyl-piperidin-1-yl)-pyrrolidine-1-sulfonyl)-phenol – selective 5-HT<sub>7</sub> receptor antagonist; SERT, serotonin transporter; SSRIs, selective serotonin reuptake inhibitors; TFMPP, 1-[m-trifluoromethylphenyl]piperazine – non-selective, but 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptor agonist; VMN, ventromedial nucleus of the hypothalamus; WAY100635, N-[2[4-(2-methoxyphenyl)-1-piperazinyl]ethyl]N-(2-pyridinyl)cyclohexanecarboxamide trihydrochloride – 5-HT<sub>1A</sub> receptor antagonist; WAY100135, chiral N-t-butyl-3-(1-(4-(2-methoxy) phenyl)piperazinyl)-1-phenylpropionamide dihydrochloride, quarter hydrate – 5-HT<sub>1A</sub> receptor antagonist, but partial agonist.

## Introduction

Serotonin (5-HT) generally exerts inhibitory control over sexual behavior, but, depending on the 5-HT receptor

subtype involved, gender, and the behavioral parameter investigated, 5-HT's role is considerably more complex. Global increases in 5-HT inhibit male or female sexual behavior while reductions in 5-HT increase sexual behavior, but effects of 5-HT receptor selective agents reveal both inhibitory and facilitatory effects (for review, see Mendelson, 1992; Uphouse, 2000; Hull *et al.*, 2004;

\*Corresponding author  
E-mail: luphouse@mail.twu.edu

de Jong *et al.*, 2006). Furthermore, effects of 5-HT vary depending on the specific aspect of sexual behavior examined. More emphasis has been placed on consummatory behavior than on sexual motivation. In the following discussion, 5-HT's contribution to male and female sexual behavior will be examined from a historical perspective, leading to current understanding of the subject. Males and females will be discussed separately, followed by an overview of the biological significance of 5-HT's role in sexual behavior and possible directions for future research.

## Female sexual behavior

### *Description of female sexual behavior*

Estrogen and progesterone coordinate the female reproductive cycle so that mating and ovulation are synchronized to optimize fertilization of the ruptured ova (Sodersten, 1981; Pfaff and Modianos, 1985). The complete repertoire of female sexual behavior includes solicitation, proceptivity (including sexual motivation) and receptivity (Sodersten, 1981; Erskine, 1989). Proceptive and solicitous behaviors advertise the female's readiness to mate. Receptivity refers to the female's consummatory response (the lordosis reflex in rodents) required for successful mating to occur. The lordosis quotient (or lordosis to mount (L/M) ratio  $\times 100$ ) has been the most commonly assessed parameter of female sexual behavior. Solicitation and proceptivity have been measured by hopping/darting and ear-wiggling in rodents, or by the female's pacing of her mating activity (Erskine, 1989). Motivated behavior has been studied primarily in the partner-preference paradigm or pacing paradigm.

The lordosis reflex is a stereotyped posture made by the female in response to displacement of mechanoreceptors in the flank, rump, tail base and perineum (Pfaff and Modianos, 1985). In non-primate mammals, hormonal priming is required for female sexual behavior to occur, and ovariectomy leads to abrupt cessation of the behavior (Sodersten, 1981; Pfaff and Modianos, 1985). In a naturally cycling female rat, both estrogen and progesterone contribute to the elicitation of sexual receptivity (Sodersten, 1981). In ovariectomized rats, estrogen, alone, facilitates lordosis behavior, but progesterone reduces the dose of estrogen priming that is required and is essential for the full repertoire of female sexual behavior (Sodersten, 1981).

The basic neuronal circuitry for lordosis is contained in the spinal cord. An abbreviated lordosis response can be obtained in a spinal preparation (McKenna *et al.*, 1991a), but forebrain areas are required for complete expression of the reflex (Pfaff and Modianos, 1985). Many brain areas contribute to the complete behavioral repertoire of the

sexually receptive female (Cottingham and Pfaff, 1986; Daniels *et al.*, 1999; Flanagan-Cato *et al.*, 2006), but diencephalic sites (including the preoptic area, POA, and ventromedial nucleus of the hypothalamus, VMN), midbrain and brainstem sites are crucial for hormonal control of lordosis (Pfaff and Modianos, 1985; Daniels and Flanagan-Cato, 2000; Flanagan-Cato *et al.*, 2006). Input from multiple brain areas converges in the VMN (Cottingham and Pfaff, 1986; Flanagan-Cato *et al.*, 2006), which typically has been viewed as a site where hormonal priming acts to increase the lordosis reflex (Pfaff and Modianos, 1985). Pathways from the VMN descend to the midbrain (especially to the periaqueductal gray, PAG) where integration of the sensory-motor reflex occurs (Canteras *et al.*, 1994; Daniels *et al.*, 1999).

### *Implications for a role of 5-HT in female sexual behavior*

Early investigators noted that the administration of drugs such as reserpine, tetrabenazine or parachlorophenylalanine (PCPA), which reduce the overall concentration of monoamines, activated lordosis in estrogen-primed, ovariectomized females as effectively as did progesterone. Moreover, a variety of non-selective 5-HT receptor antagonists were reported to increase consummatory, but not solicitous, behavior. A thorough review of these early studies can be found in Mendelson (1992). In general, any treatment which reduced 5-HT activity or which decreased overall monoamine concentrations increased lordosis, while treatments that increased 5-HT activity reduced the lordosis reflex. However, drug effects interact with the nature and degree of hormonal priming, with both estrogen and progesterone offering some protection against the effects of serotonergic agents (Trevino *et al.*, 1999; Jackson and Etgen, 2001; Sinclair-Worley and Uphouse, 2004).

Direct infusion of 5-HT or 5-HT-active compounds into various brain areas implicated the mediobasal hypothalamus (MBH) (especially the VMN) as a site where 5-HT-mediated inhibition occurred (Foreman and Moss, 1978; Allen *et al.*, 1993; Frankfurt *et al.*, 1994), and it was suggested that 5-HT levels in the MBH were inversely correlated with lordosis (Luine and Paden, 1982; Allen *et al.*, 1993; Farmer *et al.*, 1996). Consistent with this suggestion, a reduction of 5-HT input to the MBH by lesioning of 5-HT neurons with 5,7-dihydroxytryptamine (5,7-DHT) reduced the dose of estrogen that was required to facilitate the lordosis reflex (Luine *et al.*, 1984; Frankfurt *et al.*, 1985), and this enhanced response to estrogen was lost when 5-HT axons reinnervated the hypothalamus (Frankfurt *et al.*, 1994). Moreover, the concentration of

5-HT available to activate postsynaptic receptors in the MBH declines near the time of sexual receptivity (Farmer *et al.*, 1996; Maswood *et al.*, 1999). Progesterone, after estrogen priming, rather than estrogen alone, may be responsible for the 5-HT decline (Gereau *et al.*, 1993; Farmer *et al.*, 1996; Maswood *et al.*, 1999; Lu and Bethea, 2002). However, estrogen may influence the temporal availability of 5-HT by modulation of 5-HT reuptake into nerve terminals (McQueen *et al.*, 1997; Bethea *et al.*, 2002; Bertrand *et al.*, 2005; Benmansour *et al.*, 2008).

If an increase in 5-HT decreases sexual behavior, then blocking the serotonin transporter (SERT) should reduce sexual behavior. This was appreciated in early studies with non-specific monoamine reuptake inhibitors, and later with selective serotonin reuptake inhibitors (SSRIs). Due to the sexual dysfunction associated with their use, there has been resurgence in interest regarding SSRIs, which are used to treat a variety of mood disorders especially prevalent in women (Gregorian *et al.*, 2002; Montgomery *et al.*, 2002). In animal studies, both acute and chronic treatment with SSRIs reduces female rat lordosis behavior but there is considerable variation in the timing and magnitude of the response (Matuszczyk *et al.*, 1998; Frye *et al.*, 2003; Sarkar *et al.*, 2008a). For example, Matuszczyk *et al.* (1998) treated ovariectomized rats daily with 10 mg/kg fluoxetine, and tested sexual behavior after weekly priming with estrogen and progesterone. Effects on sexual receptivity were small, and did not develop until approximately 21 days of treatment. In contrast, a single treatment with fluoxetine reduced lordosis behavior in hormonally-primed, ovariectomized female rats (Frye *et al.*, 2003; Sarkar *et al.*, 2008a) and lateral displacement in female hamsters (Frye and Rhodes, 2003). After longer treatment in rats, fluoxetine's inhibitory effects were attenuated (Frye *et al.*, 2003; Sarkar *et al.*, 2008a). These findings differ from the human literature, where sexual side effects are often reported to continue through the duration of SSRI treatment. However, few studies have been designed to evaluate human female sexual activity prior to the onset of SSRI treatment. Some investigators report improvement after chronic fluoxetine treatment, while others report continued sexual dysfunction.

The degree to which SSRI effects on the neuroendocrine system contribute to their effects on sexual behavior in rodent models is still uncertain, and little information is available in the human population. In animal models, some investigators have reported normal estrous cyclicity when female rats were treated daily with fluoxetine (Matuszczyk *et al.*, 1998; Heisler *et al.*, 1999; Van de Kar *et al.*, 2002), while disruption of estrous cyclicity and sexual behavior was reported in Fischer female rats, with the implication that the SSRI's effect on sexual behavior was not independent from the estrous cycle disruption

(Uphouse *et al.*, 2006; Sarkar *et al.*, 2008b). However, strain differences may account for the variable findings (Maswood *et al.*, 2008). Neural sites responsible for SSRI-induced female sexual behavior have not been identified, but effects have been attributed to CNS and/or peripheral effects of the SSRI-induced elevation in 5-HT (Clayton, 2002; Frohlich and Meston, 2005). Additional studies will be required to determine if sexual behavioral effects are the direct result of elevations in CNS 5-HT, or consequences of endocrine or other peripheral or neural modifications that occur following treatment with SSRIs.

### **5-HT receptors and female consummatory behaviors**

The 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>2A/2C</sub>, 5-HT<sub>3</sub> and 5-HT<sub>7</sub> receptors have been implicated in the modulation of lordosis behavior. The 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families have received the most attention, leading to the conclusion that activation of 5-HT<sub>1A</sub> receptors inhibits lordosis behavior while activation of 5-HT<sub>2</sub> receptors facilitates the reflex (for review, see Mendelson, 1992; Uphouse, 2000). Similar to 5-HT<sub>1A</sub> receptors, 5-HT<sub>7</sub> receptors may also inhibit lordosis behavior (Siddiqui and Shaharyar, 2007; Siddiqui *et al.*, 2007). Activation of the ligand-gated 5-HT<sub>3</sub> receptor in the MBH may facilitate lordosis behavior (Maswood *et al.*, 1997, 1998), but systemic treatments with 5-HT<sub>3</sub> receptors agonists have generally been ineffective in altering the lordosis response (Tanco *et al.*, 1993, 1994).

#### **5-HT<sub>1A</sub> receptors**

Several investigators have reported that systemic administration of 5-HT<sub>1A</sub> receptor agonists reduced lordosis behavior of ovariectomized females, hormonally primed with estrogen or with estrogen and progesterone, and effects were attenuated by a variety of 5-HT<sub>1A</sub> receptor antagonists (for review, see Mendelson, 1992; Uphouse, 2000). Since systemic administration of 5-HT<sub>1A</sub> receptor agonists activates 5-HT<sub>1A</sub> receptors that are postsynaptic to 5-HT terminals as well as 5-HT<sub>1A</sub> somatodendritic autoreceptors, localization of the effective sites is important in understanding the role of 5-HT in the modulation of lordosis behavior. At the postsynaptic target, 5-HT<sub>1A</sub> receptor agonists simulate effects of increased 5-HT release from nerve terminals. However, at soma and dendrites of 5-HT neurons, activation of 5-HT<sub>1A</sub> autoreceptors decreases firing of 5-HT neurons and decreases release of 5-HT from synaptic terminals (Sprouse and Aghajanian, 1987; Hjorth and Sharp, 1991; Adell *et al.*, 1993). Low doses of ipsapirone or gespirone, but not other 5-HT<sub>1A</sub> receptor agonists, were reported to facilitate lordosis behavior of ovariectomized rats primed

only with estrogen, but not in rats primed with estrogen and progesterone (Mendelson and Gorzalka, 1986a,b). Because somatodendritic 5-HT<sub>1A</sub> autoreceptors may be especially sensitive to 5-HT<sub>1A</sub> receptor agonists (Kennett *et al.*, 1987; Beer *et al.*, 1990), facilitation of lordosis behavior after a low dose of these drugs might reflect activation of somatodendritic autoreceptors and a consequent reduction of 5-HT release in terminal fields. To our knowledge, direct application of a low dose of 5-HT<sub>1A</sub> receptor agonists to the somatodendritic autoreceptors has not been examined in a suboptimally hormone-primed animal, so the importance of these autoreceptors to potential facilitation of lordosis behavior has yet to be determined.

Direct infusion of the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT (8-hydroxy-2-(di-N-propylamino) tetralin) into the dorsal raphe nucleus (DRN) had no effects on lordosis behavior of sexually receptive female rats (Uphouse *et al.*, 1992). However, some decline was evident following infusion of 8-OH-DPAT into the median raphe nucleus (MRN) (Uphouse *et al.*, 1994a). In contrast, infusion of 8-OH-DPAT into regions terminal to 5-HT neurons produced robust inhibition of lordosis behavior (Gonzalez *et al.*, 1997; Uphouse, 2000). Moreover, inhibition was observed in rats with intrahypothalamic 5,7-dihydroxytryptamine (5,7-DHT) lesions (Aiello-Zaldivar *et al.*, 1992) or in rats with lesions of the DRN (Kishitake and Yamanouchi, 2005). Effective sites for 5-HT<sub>1A</sub> receptor agonists include the medial preoptic area (mPOA), VMN, and ventrolateral PAG (Gonzalez *et al.*, 1997; Uphouse, 2000; Caldwell and Albers, 2002), while infusion into the dorsal or anterior hypothalamus (AH) is relatively ineffective (Gonzalez *et al.*, 1997; Trevino *et al.*, 1999; Guptarak *et al.*, 2004). Of terminal areas, the VMN is the brain region in the rat where the lowest dose of 8-OH-DPAT inhibits lordosis behavior. For this brain area, Uphouse and colleagues have argued that the 5-HT<sub>1A</sub> receptor provides a brake on sexual receptivity under conditions of high risk to the female (Uphouse, 2000). However, in female hamsters, infusion of 8-OH-DPAT into the mPOA-AH reduced mean lordosis duration but increased the number of lordosis episodes during the observation session (Caldwell and Albers, 2002). These authors suggested a role for mPOA 5-HT<sub>1A</sub> receptors in the regulation of the temporal pacing of lordosis.

If activation of 5-HT<sub>1A</sub> receptors tonically decreases lordosis behavior, treatment with 5-HT<sub>1A</sub> receptor antagonists might increase lordosis. The selective 5-HT<sub>1A</sub> receptor antagonist WAY100635 (N-[2[4-(2-methoxyphenyl)-1-piperazinyl]ethyl]N-(2-pyridinyl)cyclohexanecarboxamide trihydrochloride) did increase lordosis in ovariectomized rats that had a low initial sexual receptivity (Kishitake and Yamanouchi, 2004), but when suboptimally hormonally-primed, ovariectomized rats received VMN

infusion with WAY100635, lordosis behavior was not facilitated (Uphouse and Wolf, 2004). However, some facilitation was observed following infusion with the partial agonist WAY100135 (chiral N-t-butyl-3-(1-(4-(2-methoxy) phenyl)piperazinyl)-1-phenylpropionamide dihydrochloride, quarter hydrate) (Uphouse *et al.*, 1996). The effects of a 5-HT<sub>1A</sub> receptor antagonist may vary as a function of the female's initial level of receptivity (e.g., if receptivity is too low, facilitation may not be possible; and if receptivity is high, a further increase is not possible). Nevertheless, 5-HT<sub>1A</sub> receptors do not appear to exert tonic inhibition of lordosis behavior but may increase the lordosis threshold. In that case, a 5-HT<sub>1A</sub> receptor antagonist could reduce the amount of estrogen and progesterone priming required to facilitate the reflex. Such a change in sensitivity to estrogen priming is thought to be responsible for the enhanced lordosis seen after 5,7-DHT lesion (Frankfurt *et al.*, 1985; Luine *et al.*, 1987). However, this hypothesis has not been tested directly.

The potency of 5-HT<sub>1A</sub> receptor agonists for inhibiting sexual behavior does, however, decrease with an increase in hormonal priming, and both estrogen and progesterone appear to be contributors (Jackson and Uphouse, 1998; Jackson and Etgen, 2001; Truitt *et al.*, 2003). Although estrogen does not alter the density of 5-HT<sub>1A</sub> receptors (Jackson and Etgen, 2001; Landry and Di Paolo, 2003), it may reduce receptor coupling to effector G-proteins (Raap *et al.*, 2000; Mize *et al.*, 2003) and thereby alter the effectiveness of the 5-HT<sub>1A</sub> receptor agonists.

While there is general agreement about the inhibitory effects of 8-OH-DPAT on female sexual behavior in a variety of species, facilitation of sexual receptivity was reported in the female ferret (Paredes *et al.*, 1994). The opposite effect of the drug in ferrets and rats may reflect a species difference in the response to the drug (e.g., male ferrets also respond to 8-OH-DPAT in a manner opposite to that of rats; see male sexual behavior section below). Whether this reflects species differences in the behavioral pattern typical of sexual behavior, a difference in neuronal circuitry underlying the control of sexual behavior, or different pharmacokinetics of the drug is uncertain.

Since 8-OH-DPAT also has affinity for 5-HT<sub>7</sub> receptors (Cornfield *et al.*, 1991), it is difficult to exclude 5-HT<sub>7</sub> receptors in all the reported inhibitory effects of 8-OH-DPAT. However, pindolol blocked the effects of systemic 8-OH-DPAT treatment, and in the VMN, 5-HT<sub>7</sub> receptors probably make minimal contribution to the effects of 8-OH-DPAT. In this brain area, both WAY100635 and pindolol, neither of which are active at 5-HT<sub>7</sub> receptors (Lovenberg *et al.*, 1993; Fletcher *et al.*, 1996), attenuated effects of 8-OH-DPAT (Uphouse *et al.*, 1996; Uphouse and Wolf, 2004).

In summary, most evidence is consistent with an inhibitory role of 5-HT<sub>1A</sub> receptors in female sexual

behavior, and receptors postsynaptic to 5-HT terminals appear to mediate the inhibitory effect.

#### 5-HT<sub>1B</sub> receptors

Since terminal 5-HT<sub>1B</sub> receptors function as autoreceptors to control 5-HT release (Sari, 2004), they might be expected to play a positive role in control of lordosis behavior. In early experiments with non-selective 5-HT<sub>1B</sub> receptor agonists such as mCPP (1-(m-chlorophenyl) piperazine) or TFMPP (1-[m-trifluoromethyl-phenyl]piperazine), increases in lordosis behavior were reported (for review, see Mendelson, 1992). In rats with intrahypothalamic 5,7-DHT lesions, TFMPP facilitated lordosis behavior (Aiello-Zaldivar *et al.*, 1992) and infusion of TFMPP into the VMN of suboptimally-hormone primed rats increased lordosis behavior (Wolf *et al.*, 1998). However, Wolf *et al.* (1998) attributed these effects to actions of TFMPP at 5-HT<sub>2</sub> receptors. Since most of the drugs originally implicating 5-HT<sub>1B</sub> receptors in lordosis behavior also share agonist action at multiple 5-HT receptors (Sari, 2004), the role of 5-HT<sub>1B</sub> receptors has been difficult to identify.

However, recently the 5-HT<sub>1B/1D</sub> receptor antagonist N-[4-methoxy-3-(4-methyl-1-piperazinyl)phenyl]-2'-methyl-4'-(5-methyl-1,2,4-oxadiazol-3-yl)-1-1'-biphenyl-4-carboxamide hydrochloride (GR 127935) was found to inhibit lordosis behavior of ovariectomized rats, hormonally primed only with estrogen (Uphouse *et al.*, 2008). No effects were present in rats hormonally primed with estrogen and progesterone. Although these findings are consistent with earlier speculations for a facilitatory effect of 5-HT<sub>1B</sub> receptors (Mendelson, 1992), additional work is required before such a role can be definitively identified. In particular, since GR 127935 can act as a partial agonist under some conditions (Beer *et al.*, 1998; de Groote *et al.*, 2003), it is imperative that additional selective 5-HT<sub>1B</sub> receptor drugs be examined.

#### 5-HT<sub>2</sub> receptors

A possible lordosis-facilitatory role for 5-HT<sub>2A/2C</sub> receptors stemmed from findings that systemic treatment with non-selective 5-HT<sub>2A/2C</sub> receptor antagonists inhibited lordosis in ovariectomized rats, hormonally primed with estrogen or with estrogen and progesterone, and that 5-HT<sub>2A/2C</sub> receptor agonists facilitated lordosis in ovariectomized rats primed only with estrogen (for review, see Mendelson, 1992). Intracranial studies with the 5-HT<sub>2A/2C</sub> receptor selective agonist DOI ((+/-)-1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane HCl) support such a facilitative role (Gonzalez *et al.*, 1997; Wolf *et al.*, 1998). However, in females that were already sexually receptive, DOI did not alter lordosis behavior but increased hopping and darting behavior (Rossler *et al.*, 2006). Since females

showed high L/M ratios (0.7–0.8) prior to treatment with DOI, additional facilitation may not have been observable.

The VMN (Wolf *et al.*, 1998) and mPOA (Gonzalez *et al.*, 1997) have been implicated as neural sites where 5-HT<sub>2</sub> receptor-mediated facilitation of lordosis occurs, but it remains unclear if 5-HT<sub>2A</sub> or 5-HT<sub>2C</sub> receptors are responsible. The 5-HT<sub>2A</sub> receptor antagonist MDL 100907 ((±)-2,3-dimethoxyphenyl)-1-[2-(4-piperidine) methanol] did not alter the effect of DOI following infusion into the VMN, but the selective 5-HT<sub>2C</sub> receptor antagonist SB206553 (N-3-pyridinyl-3,5-dihydro-5-methyl-benzo (1,2-b:4,5-b')dipyrrole-(2H)carboxamide) reduced the facilitation (Wolf *et al.*, 1999). However, in the mPOA, facilitatory effects of DOI were attributed to activation of 5-HT<sub>2A</sub>, rather than 5-HT<sub>2C</sub>, receptors (Gonzalez *et al.*, 1997). In female hamsters, infusion of DOI into the mPOA-AH increased mean lordosis duration but reduced the number of lordosis episodes, and there was no effect of mCPP. Since mCPP has agonist action at 5-HT<sub>2C</sub> receptors, these authors concluded that it was the 5-HT<sub>2A</sub>, and not the 5-HT<sub>2C</sub>, receptor that was critical to the mPOA facilitation in hamsters (Caldwell and Albers, 2002). Given the potential role of the mPOA in female rat sexual motivation (Guarraci *et al.*, 2004) and the established role for the VMN in lordosis behavior (Pfaff and Modianos, 1985), it is possible that 5-HT<sub>2A</sub> receptors in the mPOA are important for sexual motivation while 5-HT<sub>2C</sub> receptors in the VMN facilitate lordosis behavior. Additional studies are required to pursue these possibilities.

#### 5-HT<sub>3</sub> receptors

5-HT<sub>3</sub> receptor antagonists were initially reported to have no effect on sexual behavior of sexually receptive females, but to increase lordosis in non-receptive rats (discussed in Tanco *et al.*, 1993). In an attempt to replicate these initial findings, no effects of 5-HT<sub>3</sub> receptor active compounds were found (Tanco *et al.*, 1993, 1994). In contrast, a substantial decline of lordosis behavior and lordosis quality was found in hormonally primed ovariectomized rats after VMN infusion of the 5-HT<sub>3</sub> receptor antagonist tropisetron, and effects were attenuated by co-infusion with the 5-HT<sub>3</sub> receptor agonist m-chlorophenylbiguanide, but in proestrous rats, the inhibitory effects of tropisetron were not dose-dependent and showed a considerably lower potency (Maswood *et al.*, 1997, 1998). However, a facilitatory role for the 5-HT<sub>3</sub> receptor in the periphery has been suggested (McKenna *et al.*, 1991b). These authors argued that the 5-HT<sub>3</sub> receptor might sensitize sensory fibers and thereby reduce the amount of stimulation required to elicit the reflex (McKenna *et al.*, 1991b).

In summary, in comparison to the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> family of receptors, the ligand-gated 5-HT<sub>3</sub> receptor may play a minor role in female sexual behavior. Nevertheless,

given the paucity of attempts to identify any potential role for 5-HT<sub>3</sub> receptors in female sexual behavior, their apparent lack of importance to the behavior should be evaluated cautiously.

### 5-HT<sub>7</sub> receptors

To our knowledge, only two studies have been designed to evaluate effects of 5-HT<sub>7</sub> receptors on lordosis behavior. In each, the authors based their conclusions upon a comparison of effects of 8-OH-DPAT and 5-CT (5-carboxyamidetryptamine) (Siddiqui and Shaharyar, 2007; Siddiqui *et al.*, 2007). Both drugs reduced lordosis behavior, and the 5-HT<sub>1A</sub> receptor antagonist (partial agonist) WAY100135 attenuated the decline. A 5-HT<sub>7</sub> receptor antagonist, SB269970A (2-(2-(4-methyl-piperidin-1-yl)-pyrrolidine-1-sulfonyl)-phenol), attenuated effects of 5-CT but not of 8-OH-DPAT. In non-receptive rats, both WAY100135 and SB 269970A produced a slight facilitation of lordosis behavior. These investigators concluded that activation of the 5-HT<sub>7</sub> receptor may inhibit female sexual behavior like 5-HT<sub>1A</sub> receptors, and, similar to the effects of estrogen on 5-HT<sub>1A</sub> receptors, the effects of 5-CT were partially attenuated by a high dose of estrogen (Siddiqui and Shaharyar, 2007; Siddiqui *et al.*, 2007).

### Receptor interaction

Although it has been convenient to attempt to dissect the influence of the various 5-HT receptors to the neurotransmitter's modulation of female sexual behavior, it is, at best, an imprecise view of the endogenous role played by 5-HT. Endogenous 5-HT acts upon all available 5-HT receptors so that the net behavioral outcome is a composite of all the information received from receptor activation. For example, while 8-OH-DPAT inhibits lordosis behavior following infusion into the VMN, co-infusion with either 5-HT<sub>2</sub> receptor agonists or a 5-HT<sub>3</sub> receptor agonist can prevent the lordosis inhibition (Uphouse *et al.*, 1994b; Maswood *et al.*, 1998). Similarly, the 5-HT<sub>2A/2C</sub> receptor agonist DOI can attenuate the reduction in lordosis behavior initiated by the 5-HT<sub>3</sub> receptor antagonist, tropisetron (Maswood *et al.*, 1998). Therefore, composite effects of the individual receptors are likely to provide important clues as to how the endogenous system is actually functioning.

It is also increasingly clear that peripheral effects of 5-HT contribute to the neurotransmitter's modulation of female sexual behavior (Frohlich and Meston, 2000). Emphasis on central mechanisms has been important in identifying sites and mechanisms of action responsible for CNS mediation of the behavioral change in response to 5-HT, but in the human population, pharmaceutical agents

modifying 5-HT function are administered systemically; therefore, the contribution of peripheral events is equally important (Frohlich and Meston, 2000, 2005).

### 5-HT and female sexual motivation

There have been surprisingly few studies designed to examine effects of 5-HT on female sexual motivation. In a pacing paradigm, when the latency for females to return to the male after an ejaculation was examined, PCPA increased the return duration, interpreted as a reduction in sexual motivation (Emery and Moss, 1984). However, given the potential effects of 5-HT on vaginal sensitivity and/or response to stimuli (Frohlich and Meston, 2000), it is difficult to conclude that control and experimental females received equivalent sensory stimuli.

In a partner-preference paradigm, however, the SSRI fluoxetine was reported to reduce the female's preference for spending time with the male (Matuszczyk *et al.*, 1998). The difference was present only at the first test, after 7 days of fluoxetine treatment; thereafter, male preference scores for the control females declined to the same level as the fluoxetine-treated group and remained relatively constant for the duration of treatment. A fluoxetine-induced decline in lordosis behavior did not develop for at least 7 days after the first male preference test.

In contrast to the study by Matuszczyk *et al.* (1998), Sarkar *et al.* (2008a) found no decline in male preference scores when fluoxetine-treated, ovariectomized rats were hormonally primed with estrogen and progesterone. The differences in these findings may reflect the use of intact rats by Matuszczyk *et al.* (1998) and ovariectomized rats by Sarkar *et al.* (2008a). If, as previously suggested (Uphouse *et al.*, 2006), fluoxetine has the potential to disrupt the normal hormonal events that drive the reproductive cycle, estrogen and progesterone priming may have overridden the effects of fluoxetine on male preference. However, Maswood *et al.* (2008) failed to find a change in male preference after 10 days of fluoxetine treatment in intact female rats.

Given the current interest in drug-induced disruption of female sexual desire and satisfaction, additional studies are warranted in order to understand the potential involvement of serotonergic mechanisms to female sexual motivation.

### Summary

It is now well established that female consummatory sexual behavior is reduced by activation of 5-HT<sub>1A</sub> receptors and possibly increased by activation of 5-HT<sub>2A/2C</sub>

receptors. The definitive role for 5-HT<sub>1B</sub> and 5-HT<sub>3</sub> receptors remains to be determined. Female sexual motivation has received far less attention, and should receive greater emphasis in future studies. Finally, there is no information about any potential role of the 5-HT<sub>4</sub>, 5-HT<sub>5</sub> or 5-HT<sub>6</sub> receptors in female sexual activity.

## Male sexual behavior

### *Description of male sexual behavior*

Male sexual behavior, including appetitive (sexual motivation; recognition and approach to a sexually relevant partner) and consummatory (copulatory) activities, is controlled by both central and peripheral mechanisms (Cruz *et al.*, 1999; Giuliano and Rampin, 2004; de Jong *et al.*, 2006; Hull and Dominguez, 2007). Mating culminates with ejaculation, which is followed by a post-ejaculatory interval during which the male shows little interest in his sexual partner. The lumbosacral spinal cord houses the sensory-motor circuitry required for ejaculation (Truitt and Coolen, 2002; Allard *et al.*, 2005), while supraspinal control is inhibitory to the reflex (Coolen *et al.*, 2004; Allard *et al.*, 2005; de Jong *et al.*, 2006). Information from forebrain areas is transmitted to the spinal cord via the PAG and then to the nucleus paragigantocellularis (nPGi) of the medulla (Rizvi *et al.*, 1996; Marson and Gravitt, 2004). In spinal-cord transected, anesthetized rats, a 'urethrogenital reflex' (muscle contraction and urethral expulsion) can be elicited (McKenna *et al.*, 1991b). However, the reflex can also be elicited in rats with lesion of the nPGi (Marson and McKenna, 1990) or by stimulation of the mPOA (Marson and McKenna, 1994). Therefore, supraspinal information, probably derived from the nPGi, tonically inhibits the ejaculation reflex (de Jong *et al.*, 2006) while the mPOA, via a relay to the PAG, reduces this tonic inhibition and thereby reduces the ejaculatory threshold, facilitating ejaculation (de Jong *et al.*, 2006). Critical sites for descending control of ejaculation include the mPOA, paraventricular nucleus (PVN), PAG and nPGi (Giuliano, 2007). The mPOA, likely via projections to the PAG, influences descending information to the spinal cord and is a critical site for integrating the complex sensory and motor information involved in copulation (Mas, 1995; Hull and Dominguez, 2007). Appetitive behavior is influenced by the mPOA, nucleus accumbens and additional brain areas (Pfaus and Phillips, 1991; Paredes *et al.*, 1993, 1998; Mas, 1995; Pfaus *et al.*, 1995). The anterior lateral hypothalamus may be important in the cessation of sexual behavior that occurs during the post-ejaculatory interval (Mas, 1995; Hull *et al.*, 1999).

Male sexual behavior requires a minimal amount of testosterone priming. Adult castration leads to a decline in testosterone over a few days, while sexual behavior declines at a slower rate, depending on prior sexual experience (Hull and Dominguez, 2007). Sexual behavior can be restored by hormonal priming with testosterone (McGinnis *et al.*, 1989), which is metabolized via aromatization to estrogen, or via 5-alpha reductase to dihydrotestosterone (DHT) (Wilson *et al.*, 1993; Wilson, 1999). Both metabolites are required to produce the full repertoire of male sexual behavior (McGinnis and Dreifuss, 1989; Vagell and McGinnis, 1997; Putnam *et al.*, 2003).

### *Implications for a role of 5-HT in male sexual behavior*

An inhibitory effect of serotonin on male sexual behavior has been appreciated since the 1970s, with observations that various treatments which increased serotonin led to a reduction in copulatory behavior. Excellent prior reviews are available (Hull *et al.*, 2004; de Jong *et al.*, 2006). Like female sexual behavior, evaluation of the consummatory response has dominated the study of male sexual behavior. When male sexual motivation has been the focus of interest, investigators have used the partner-preference paradigm, conditioned place preference, or sexual motivation has been inferred from the latency to ejaculate.

Although different in their time-course and effectiveness, most agents that elevate 5-HT reduce ejaculation efficiency (i.e., increase the number of intromissions preceding ejaculation) and/or increase ejaculation latency (i.e., delay ejaculation), while reductions in 5-HT generally facilitate sexual behavior (Hull *et al.*, 2004; de Jong *et al.*, 2006). However, in anesthetized and spinally-transected rats, 5-HT may exert a facilitatory influence on penile reflexes such as erection and ejaculation (Rehman *et al.*, 1999; Yonezawa *et al.*, 2000) and may even elicit erection in intact, non-anesthetized models (Millan and Perrin-Monneyron, 1997).

5-HT enhancing agents have included the 5-HT precursor 5-hydroxytryptophan (5-HTP), parachloramphetamine or fenfluramine, which lead to release of 5-HT from nerve terminals, or SSRIs, which increase 5-HT by blocking reuptake into the nerve terminal. Procedures to reduce 5-HT activity have included lesioning of 5-HT neurons with 5,7, DHT, inhibition of 5-HT synthesis, or a variety of 5-HT receptor antagonists (for review, see Hull *et al.*, 2004; de Jong *et al.*, 2006). In the anterior lateral hypothalamic area, 5-HT increases following ejaculation and may contribute to the reduced sexual behavior during the post-ejaculatory interval (Lorrain *et al.*, 1997).

Serotonin's inhibitory effects on copulation occur throughout the central nervous system, because direct

application of 5-HT to a variety of areas, including the nucleus accumbens (Hillegaart *et al.*, 1991), mPOA (Verma *et al.*, 1989), DRN or MRN (Hillegaart *et al.*, 1989) and spinal cord (Svensson and Hansen, 1984; Mas *et al.*, 1985), inhibit copulation. However, facilitatory effects of a low concentration of 5-HT in DRN or MRN reduced ejaculation latency and number of intromissions to ejaculation (Hillegaart *et al.*, 1989), and an increase in copulation was reported after 5-HT application to the MRN but not DRN (Larsson and Ahlenius, 1999). Facilitatory effects of 5-HT in raphe regions may reflect autoinhibitory effects of 5-HT and consequent reduction of 5-HT's release in terminal areas. Evidence that lesions of the MRN significantly enhanced male sexual behavior is consistent with this possibility (reviewed in Larsson and Ahlenius, 1999).

Of the agents that modify 5-HT, SSRIs have been of special interest because of their effectiveness in the treatment of premature ejaculation in humans (Waldinger *et al.*, 2005). Individuals being treated with SSRIs for depression often develop sexual dysfunction, evidenced as a delay in or prevention of ejaculation (Waldinger and Olivier, 1998; Gregorian *et al.*, 2002; Montgomery *et al.*, 2002; Nurnberg, 2008). This undesirable side effect is of therapeutic advantage for individuals with premature ejaculation (Waldinger and Olivier, 2004; Waldinger, 2005; Mercado *et al.*, 2008). However, the mechanisms responsible for these effects of SSRIs remain unclear. In spite of comparable enhancement of extracellular 5-HT, SSRIs vary in their ability to delay ejaculation (Waldinger *et al.*, 1998; Waldinger and Olivier, 2004). Furthermore, clinical improvement of premature ejaculation requires weeks of treatment with SSRIs (Waldinger *et al.*, 1998; Waldinger *et al.*, 2005), while an increase in extracellular 5-HT is more rapid in onset (Gobert *et al.*, 1997; Tao *et al.*, 2000; Felton *et al.*, 2003).

In animal studies, an ejaculatory delay after acute treatment with SSRIs has been reported by some investigators (Yells *et al.*, 1994, 1995; Lorrain *et al.*, 1997), but most have not seen such acute effects (Waldinger *et al.*, 2002; de Jong *et al.*, 2005a,b). This may be a function of the use of different SSRIs and/or differences in the precise experimental procedures and/or route of administration of the SSRIs. Nevertheless, repeated treatment with SSRIs is clearly more effective than a single treatment in delaying ejaculation. Because chronic treatment with SSRIs leads to downregulation/desensitization of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors (Hensler, 2003; Newman *et al.*, 2004), some investigators have argued that the ability of SSRIs to delay ejaculation requires the desensitization of these receptors (de Jong *et al.*, 2006). This argument is particular appealing, given the facilitatory role of 5-HT<sub>1A</sub> receptors and putative inhibitory role of 5-HT<sub>1B</sub> receptors in male sexual behavior (see below). Evidence that chronic treatment

with the SSRI paroxetine attenuated some, but not all, effects of a 5-HT<sub>1A</sub> receptor agonist on sexual behavior provides some evidence in support of this idea (de Jong *et al.*, 2005c). However, with newer, short-acting reuptake inhibitors such as dapoxetine, effects in patients suffering from premature ejaculation may be seen within hours (Clement *et al.*, 2007; Giuliano, 2007; Kendirci *et al.*, 2007; Wang *et al.*, 2007). Effects of SSRIs on male ejaculation probably result primarily from actions of the drugs in the CNS (de Jong *et al.*, 2005b), but peripheral effects cannot be ruled out (Medina *et al.*, 2000; Giuliano, 2007).

Effects of SSRIs on non-contact penile erections have been varied, with some investigators reporting fluoxetine-induced increases (Simon *et al.*, 1993; Millan and Perrin-Monneyron, 1997) and others reporting decreases after treatment (Sukoff Rizzo *et al.*, 2008). While the explanation for these differences is unclear, it appears that when the level of spontaneous erections is low, erections are increased by fluoxetine. If spontaneous erections are high, they may be reduced by fluoxetine.

### ***Receptors and male sexual behavior***

With the available collection of pharmaceutical agents and molecular tools, the most coherent story is that 5-HT<sub>1A</sub> receptor agonists can inhibit or facilitate copulation in a species-dependent manner (e.g., facilitation in rats and inhibition in mice); the 5-HT<sub>1B</sub> receptor inhibits copulation but may facilitate penile erections. The 5-HT<sub>2</sub> receptors reduce ejaculation but increase (via 5-HT<sub>2C</sub> receptor) penile erection. The 5-HT<sub>3</sub> receptor plays a minor, if any, role in male sexual behavior.

#### ***5-HT<sub>1A</sub> receptors***

Activation of 5-HT<sub>1A</sub> receptors increases ejaculation in rats but decreases it in mice. In rats, 5-HT<sub>1A</sub> receptors facilitate male sexual behavior by delaying ejaculation latency, but reduce spontaneous penile erections (Schnur *et al.*, 1989; Looney *et al.*, 2005; de Jong *et al.*, 2006). The first report of facilitation in rats was in 1981 (Ahlenius *et al.*, 1981), and was rapidly followed by additional studies indicating that a variety of 5-HT<sub>1A</sub> receptor agonists reduced ejaculatory latency in rats but did not enhance motivational indices such as mounting or intromission latency (for review, see Hull *et al.*, 1999, 2004; de Jong *et al.*, 2006). Facilitatory effects were blocked with 5-HT<sub>1A</sub> receptor antagonists (Ahlenius and Larsson, 1991; Hillegaart and Ahlenius, 1998), including the selective 5-HT<sub>1A</sub> receptor antagonist WAY100635 (Ahlenius and Larsson, 1998). Alone, WAY100635 did not alter ejaculatory latency but did enhance the inhibitory effects

of agents (e.g., 5-HTP or SSRIs) that increase 5-HT (Ahlenius and Larsson, 1998, 1999; de Jong *et al.*, 2005a; Looney *et al.*, 2005).

Similarly, WAY100635, alone, had only minor effects on penile erection, but the combined blockage of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors led to a five-fold enhancement of the acute erectogenic effects of fluoxetine (Millan and Perrin-Monneyron, 1997). De Jong *et al.* (2006) argued that 5-HT<sub>1A</sub> receptors might become important only when 5-HT levels are increased. Such a possibility is interesting, given the variety of environmental challenges that can elevate 5-HT.

The most extensively studied 5-HT<sub>1A</sub> receptor agonist has been 8-OH-DPAT. Systemic 8-OH-DPAT facilitated ejaculation in intact or hormone-primed males (Mos *et al.*, 1991; Pomerantz *et al.*, 1993a; Fernandez-Guasti and Rodriguez-Manzo, 1997), antagonized the effect of 5-HTP on ejaculation (Ahlenius and Larsson, 1985) and reduced the amount of testosterone required for mating to occur (Rowland and Houtsmuller, 1998), but inhibited penile erections in dogs (Yonezawa *et al.*, 2004), rats (Schnur *et al.*, 1989; Rehman *et al.*, 1999) and monkeys (Pomerantz *et al.*, 1993b). Intrathecal administration of 8-OH-DPAT reduced penile erections and ejaculation in *ex copula* models (Schnur *et al.*, 1989; Lee *et al.*, 1990). Doses of 8-OH-DPAT that facilitated copulatory behavior reduced the weight of seminal emissions and led to the conclusion that effects of 8-OH-DPAT were not equivalent to normal copulatory/ejaculatory function (Schnur *et al.*, 1989).

In contrast to 8-OH-DPAT's facilitation of copulation in rats, 8-OH-DPAT inhibited male sexual behavior in ferrets (Paredes *et al.*, 1994), mice (Rodriguez-Manzo *et al.*, 2002) and rabbits (Paredes *et al.*, 2000). In dogs, 8-OH-DPAT reduced ejaculatory semen and increased the latency to ejaculate in response to continuous manual stimulation (Yonezawa *et al.*, 2004); in monkeys, 8-OH-DPAT's facilitation was dose-dependent, occurring only at a low dose of the drug (Pomerantz *et al.*, 1993a). At higher doses, monkeys did not initiate copulation. Explanations for these species differences remain unclear, but may reflect differences in the male's mating pattern, sensitivity to stimuli, or the relative balance between inhibitory and facilitatory 5-HT receptor families. Unfortunately, little attention has been given to the examination of these species differences.

A facilitatory effect of 5-HT<sub>1A</sub> receptor agonists on sexual behavior in rats could result from an autoreceptor-mediated reduction in extracellular 5-HT. The observation that a low dose of 8-OH-DPAT facilitated sexual behavior following infusion into the MRN provides some support for this possibility (Hillegaart *et al.*, 1991). However, no effects of 8-OH-DPAT were found following infusion into the DRN (Hillegaart *et al.*, 1991; Fernandez-Guasti *et al.*,

1992). Moreover, inhibition of 5-HT synthesis with PCPA or destruction of 5-HT cell bodies with 5,7-DHT did not block facilitatory effects of 8-OH-DPAT (Fernandez-Guasti and Escalante, 1991). Finally, direct infusion of 8-OH-DPAT into multiple brain areas that are targeted by 5-HT neurons increased copulatory behavior (Fernandez-Guasti *et al.*, 1992; Hull *et al.*, 1999, 2004; de Castilhos *et al.*, 2006; de Jong *et al.*, 2006). Consequently, postsynaptic 5-HT<sub>1A</sub> receptors are clearly included in the facilitatory effects of 5-HT<sub>1A</sub> receptor agonists on male sexual behavior in the rat.

However, in many studies with local application of 8-OH-DPAT, specificity for the 5-HT<sub>1A</sub> receptor has not been confirmed. While relatively selective for 5-HT<sub>1A</sub> receptors, 8-OH-DPAT also has affinity for other receptors. Effects of systemic 8-OH-DPAT treatment can be attenuated by 5-HT<sub>1A</sub> receptor antagonists, but comparable experiments have not been done for many intracranial studies. Confirmation that it is the 5-HT<sub>1A</sub> receptor subtype that mediates effects of direct application is badly needed, as illustrated by the finding that facilitatory effects of 8-OH-DPAT following infusion into the mPOA may not reside in its serotonergic effects (Lorrain *et al.*, 1998). Facilitatory effects of the 8-OH-DPAT infusion to the mPOA were not blocked by a 5-HT<sub>1A</sub> receptor antagonist but were blocked by a dopamine2 receptor antagonist (Lorrain *et al.*, 1998; Hull *et al.*, 1999), so that Hull and coworkers have suggested that 8-OH-DPAT's facilitatory effect in the mPOA is mediated by its effect on dopamine (Hull *et al.*, 1999, 2004).

Therefore, there is a need for greater clarification of the sites of action and receptor specificity of 5-HT<sub>1A</sub> receptor agonists on male copulatory behavior. A clear dissociation between peripheral and central effects of the drug is also needed. Effects of systemic 8-OH-DPAT on ejaculatory latency could include an enhancement of the effects of genital stimulation, since the drug can compensate for bilateral transection of the dorsal penile nerve (Dahlof *et al.*, 1988). Moreover, 5-HT<sub>1A</sub> receptor agonists, as reported for gespirone and flexinoxan, may increase the male's attractiveness to the female and thereby influence mating behavior (Mos *et al.*, 1991). These effects of 5-HT<sub>1A</sub> receptor agonists require further examination.

Consequently, in spite of general agreement about the copulation-enhancing effects of 5-HT<sub>1A</sub> receptors in some species, there is still information to be gained about the mechanisms whereby 5-HT<sub>1A</sub> receptors influence male sexual behavior.

#### 5-HT<sub>1B</sub> receptors

A variety of 5-HT<sub>1B</sub> receptor agonists have been reported to mimic the effects of 5-HT by reducing male copulatory

behavior. Many 5-HT<sub>1B</sub> receptor agonists have been investigated, but a majority of data in support of the inhibitory role for 5-HT<sub>1B</sub> receptors has been generated with TFMPP or mCPP (for review, see Hull *et al.*, 2004; de Jong *et al.*, 2006). In addition to agonist action at 5-HT<sub>1B</sub> receptors, TFMPP has agonist action at 5-HT<sub>1A</sub> and 5-HT<sub>2</sub> receptors, and mCPP is also a 5-HT<sub>2C</sub> receptor agonist, so the specificity of their effect at 5-HT<sub>1B</sub> receptors is not clear. Nevertheless, it is unlikely that 5-HT<sub>1A</sub> receptors are responsible for the inhibitory effects of TFMPP on male sexual behavior, since 5-HT<sub>1A</sub> receptor agonists facilitate sexual behavior (at least in rats). Moreover, under comparable experimental conditions, following infusion into the nucleus accumbens, the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT reduced ejaculatory latency while it was increased by TFMPP (Fernandez-Guasti *et al.*, 1992). Additionally, the effect of a 5-HT<sub>1B</sub> receptor agonist, anpirtoline, on male sexual behavior was antagonized by a 5-HT<sub>1B</sub> receptor antagonist, but not by a 5-HT<sub>1A</sub> receptor antagonist (Hillegaart and Ahlenius, 1998). Furthermore, 8-OH-DPAT reduces penile erections, while 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptor agonists increase penile erections (Berendsen *et al.*, 1990). Finally, sexual behavior of 5-HT<sub>1B</sub> receptor knockout (KO1B) mice is enhanced relative to wild-type mice and is not inhibited by either 5-HTP or TFMPP (Rodriguez-Manzo *et al.*, 2002), suggesting that these agents require the 5-HT<sub>1B</sub> receptor for their inhibition. However, 8-OH-DPAT also failed to inhibit ejaculation in KO1B mice (Rodriguez-Manzo *et al.*, 2002), raising the question of the relationship between 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors to the inhibitory effects of 5-HT in male mice. Therefore, in spite of the limited selectivity of the available 5-HT<sub>1B</sub> receptor compounds, the weight of evidence indicates that it is their activation of 5-HT<sub>1B</sub> receptors that leads to inhibition of sexual behavior. Nevertheless, data with more selective compounds are needed.

Intracranial effects of 5-HT<sub>1B</sub> receptor compounds have received less emphasis than their 5-HT<sub>1A</sub> receptor counterparts. Intracranial treatment with TFMPP in nucleus accumbens or mPOA reduced ejaculation latency (Fernandez-Guasti *et al.*, 1992), but, to our knowledge, male sexual behavior following intracranial infusion of more selective 5-HT<sub>1B</sub> receptor compounds has not been reported.

### 5-HT<sub>2</sub> receptors

5-HT<sub>2</sub> receptors were initially implicated as facilitatory to sexual behavior when the 5-HT<sub>2</sub> receptor antagonists pirenperone and ketanserin were reported to reduce the proportion of males exhibiting sexual behavior (Mendelson and Gorzalka, 1985). However, studies with

the 5-HT<sub>2A/2C</sub> selective receptor agonist DOI indicated inhibitory effects of 5-HT<sub>2</sub> receptors on male sexual behavior. DOI increased ejaculation latency and reduced the number of rats achieving ejaculation, and inhibitory effects of DOI were antagonized by 5-HT<sub>2</sub> receptor antagonists (for review, see Hull *et al.*, 2004; de Jong *et al.*, 2006). Inhibitory effects of mCPP on ejaculation, originally attributed to 5-HT<sub>1B</sub> receptor activation, are now viewed as the result of 5-HT<sub>2C</sub> receptor activation (Mendelson and Gorzalka, 1990; Pomerantz *et al.*, 1993b).

Although effects of various 5-HT releasing compounds are reversed by 5-HT<sub>2</sub> receptor antagonists (Millan *et al.*, 1997; de Jong *et al.*, 2006), inhibitory effects of 5-HTP are not (Ahlenius and Larsson, 1998), allowing the suggestion that 5-HT<sub>2</sub> receptor subtypes may differentially influence components of the male sexual response. In particular, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors may exert opposite roles in the control of copulation and penile reflexes (Lau *et al.*, 2007; Yonezawa *et al.*, 2008). For example, mCPP was recently reported to exert a biphasic effect on ejaculation and penile erections (Yonezawa *et al.*, 2008). At low doses, mCPP increased penile erection, the incidence of ejaculation, and the amount of seminal emissions. However, at higher doses, the drug inhibited both erection and ejaculation. Pro-ejaculatory effects of mCPP were attenuated by both a 5-HT<sub>2C</sub> and a 5-HT<sub>2A</sub> receptor antagonist, but only the 5-HT<sub>2C</sub> receptor antagonist reduced the effect of mCPP on penile erection (Yonezawa *et al.*, 2008).

The 5-HT<sub>2</sub> receptor subtype responsible for all the effects of 5-HT<sub>2</sub> receptor agonists is not clear, but their erectogenic effect probably relies upon activation of 5-HT<sub>2C</sub> receptors. Earlier reported effects of the erectogenic effects of mCPP have now been attributed to effects at 5-HT<sub>2C</sub> receptors (Berendsen and Broekkamp, 1990; Bagdy *et al.*, 1992), and more selective 5-HT<sub>2C</sub> receptor agents reinforce the facilitatory role of 5-HT<sub>2C</sub> receptors in penile erection (Yonezawa *et al.*, 2008). An increase in firing of nerves innervating the penis and an increased intracavernous pressure in anesthetized rats was seen following mCPP treatment (Steers and de Groat, 1989). In addition, several investigators have considered that SSRI effects on ejaculation and erection may be via increased activation of 5-HT<sub>2C</sub> receptors (Pomerantz *et al.*, 1993a; Waldinger and Olivier, 1998). A selective 5-HT<sub>2C</sub> receptor antagonist, SB 206553, abolished penile erections elicited by fluoxetine (Millan *et al.*, 1997).

The neural sites outside the spinal cord where 5-HT<sub>2</sub> receptors agonists are involved in inhibition of copulatory behavior have received minimal attention, but infusion of DOI into the amygdala increased the latency to the first ejaculation and reduced the frequency of ejaculation

(Drago *et al.*, 1999). A role for the 5-HT<sub>2A</sub> receptor in peripheral serotonergic pathways has been suggested (Lau *et al.*, 2007). Clearly, additional studies (and more selective receptor agonists and antagonists) are needed to dissect the relative contribution of the 5-HT<sub>2</sub> receptor subtypes to the modulation of male sexual behavior.

#### 5-HT<sub>3</sub> receptors

In few studies has the potential involvement of 5-HT<sub>3</sub> receptors in male sexual behavior been examined. Lau *et al.* (2007) suggested a role for peripheral 5-HT<sub>3</sub> receptors in the erectile process, but systemic treatment with 5-HT<sub>3</sub> receptor antagonists had no effect on male sexual behavior (Tanco *et al.*, 1993). Administration of a 5-HT<sub>3</sub> receptor agonist, 1-phenylbiguanide, into the lateral ventricle reduced ejaculatory latency without significant effects on other components of the behavior (Tanco *et al.*, 1994).

#### Measures of male sexual motivation

Compared to the study of copulation and penile reflexes, less emphasis has been placed on serotonin's contribution to male sexual motivation. However, under conditions where 8-OH-DPAT reduced ejaculatory latency in rats, the drug did not alter conditioned place preference following the reward of ejaculation (Camacho *et al.*, 2007). Therefore, these authors concluded that 8-OH-DPAT's facilitation of sexual behavior in male rats was not associated with an enhancement of the rewarding properties of sex.

In mice, where 8-OH-DPAT produces an inhibition of sexual behavior, the drug also produced a decline in sexual motivation, as measured by the time the male spent near a sexually receptive female (Popova and Amstislavskaya, 2002a). From a series of studies designed to examine the effects of 5-HT receptors on preference time for the female, Popova and Amstislavskaya (2002a) have concluded that, in mice, 5-HT<sub>1A</sub> and possibly 5-HT<sub>1B</sub> receptors block sexual motivation, while 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors increase sexual motivation, and at least part of the effect may be mediated by alterations in the male's testosterone response to the presence of a receptive female. In the non-contact, partner-preference paradigm, the 5-HT<sub>1A</sub> receptor agonist, 8-OH-DPAT, and the 5-HT<sub>1B</sub> receptor agonist, CGS-12066A (7-trifluoromethyl-4 (4-methyl-1-piperazinyl)-pirrolo[1,2a]quinoxaline maleate), reduced the time male mice spent near the female (Popova and Amstislavskaya, 2002a). Only 8-OH-DPAT reduced the testosterone increase that usually occurs when males are exposed to females. However, using a similar paradigm, the 5-HT<sub>2C</sub> receptor antagonist, RS 102221

(8-[5-(2,4-dimethoxy-5-(4-trifluoromethylphenyl)sulfonamido)phenyl-5-oxopentyl]-1,3,8-triazaspiro[4.5]decane-2,4-dione hydrochloride) increased the male's time near the female and increased the testosterone response (Popova and Amstislavskaya, 2002b). Ketanserin and cyproheptadine, 5-HT<sub>2A</sub> receptor-preferring antagonists, produced the reciprocal response (i.e., less time with the female and reduced testosterone response). In general agreement with these findings, DOI increased interest (i.e., increased pursuit and thrusting or increased genital sniffing) in sexual partners in prepubertal and young adult males (Padoin and Lucion, 1995).

These studies are consistent with a possible facilitatory effect of 5-HT<sub>2C</sub> receptors on sexual motivation, and also with species differences in the response to 5-HT<sub>1A</sub> receptor agonists. They further illustrate that copulatory behavior and sexual motivation are distinct behaviors, and may be independently modulated by neurally active compounds. Given the emerging interest in the sexual dysfunction resulting from treatment with a variety of therapeutic pharmaceuticals, there is an increasing need for the evaluation of serotonergic compounds on male sexual motivation.

In the few studies in which sexual motivation has been assessed during treatment with SSRIs, the consequences for sexual motivation are not consistent. When conditioned level changing in a bilevel chamber was used as the measure of sexual motivation, 10mg/kg fluoxetine reduced conditioned level changing and reduced ejaculatory responses, leading the authors to conclude that fluoxetine reduced both appetitive and consummatory responses (Cantor *et al.*, 1999).

However, daily treatment for at least 4 weeks with a low dose of fluoxetine (0.75mg/kg) failed to alter time spent with an estrous female or the number of urinary markings near the female (Taylor *et al.*, 1996). In contrast, copulatory effects became evident as early as the first week of treatment and progressed throughout the experiment. Similarly, 10mg/kg fluoxetine failed to alter the number of crossings of an electrified grill that males made to reach a receptive female, and comparable findings were obtained with trimipramine (Benelli *et al.*, 2004). In contrast, a daily dose of fluoxetine (10mg/kg) increased ejaculation latency after 9 days of treatment; preference for time spent with the female was reduced by 14 days of treatment and was eliminated by 3 weeks of treatment (Vega Matuszczyk *et al.*, 1998). However, the reduced female preference may have reflected an effect of prior experience, since rats were tested repeatedly. It was suggested that the males had developed an association between the female and the failure to ejaculate, and that this association may explain the reduction in preference for the female (Frank *et al.*, 2000). Similar to the findings

by Taylor and colleagues, Frank *et al.* (2000) reported that males chronically treated with fluoxetine continued to pursue receptive females, and therefore appeared to exhibit continued sexual motivation.

In one study with a 5-HT-depleting agent (3,4 methylenedioxymethamphetamine, MDMA, 'ecstasy'), conditioned place preference was examined (Straiko *et al.*, 2007). Rats treated with MDMA failed to form conditioned place preference for sexual reward.

## Summary

Effects of 5-HT on male sexual behavior have been studied most extensively in rats, and ejaculation and penile erection have been the primary measures of sexual activity. Evidence for an effect of 5-HT<sub>1A</sub> receptors is clearly established, but species differences are present in the direction of the effect. Identification of the mechanisms responsible for these species differences would be of value in further understanding of the serotonergic mechanisms involved in control of sexual behavior. The inhibitory effect of 5-HT<sub>1B</sub> receptors on copulation and the possible erectile effect of 5-HT<sub>2C</sub> receptors may be present across species, but the absence of substantial data with selective agonists limits understanding of the receptor subtypes involved.

## Overall summary and future directions

An inhibitory effect of 5-HT on both male and female consummatory behavior is now well established. From animal studies, as well as clinical findings, it appears that 5-HT also contributes to sexual motivation; but considerably less attention has been given to the neurotransmitter's motivational role. Furthermore, the mechanisms involved in sexual effects of 5-HT continue to be elusive, and the complete story regarding how different 5-HT receptor subtypes contribute to the modulation of sexual behavior remains to be written. In the absence of receptor-selective agonists and antagonists for many 5-HT receptors, it is still difficult to precisely define which receptor(s) mediate the divergent effects of 5-HT's effect on sexual behavior; and a majority of 5-HT receptors remain to be investigated.

Since 5-HT does not tonically inhibit most elements of sexual behavior in males or females, sexual interest does not require that 5-HT function be removed. In fact, under some conditions, activation of select 5-HT receptors may even facilitate sexual behavior. What, then, is the biological significance of 5-HT's modulation of sexual behavior? Clues to 5-HT's role can be derived from the diversity of

actions of the neurotransmitter. 5-HT exerts influence on behaviors that permit individual survival in a complex and potentially dangerous environment. The neurotransmitter contributes to behaviors such as fear, anxiety and arousal (Blier and Abbott, 2001; Carrasco and Van de Kar, 2003; Beekman *et al.*, 2005; Kitson, 2007), which allow individuals successfully to escape or adapt to threatening situations. In addition, 5-HT is involved in control of sleep, nutrient intake, and immune responses (Kaye, 2008; Nonogaki, 2008; Sanger, 2008; Vinkers *et al.*, 2008), which facilitate the organism's ability to cope with internal challenge. The neurotransmitter's modulation of sexual behavior needs to be viewed within the context of this homeostatic regulation. Rather than controlling sexual behavior *per se*, 5-HT coordinates behavioral outcomes that enhance the probability of individual survival. For example, if individuals are given the choice between satisfaction of hunger and sexual activity, sexual activity may decline. If forced to choose between escape from predation and sexual activity, individuals will choose to escape. The contribution of 5-HT to sexual behavior will therefore vary as a function of changes in internal and external demands.

For example, we have previously argued that 5-HT<sub>1A</sub> receptors reduce sexual activity under conditions of potential threat (Uphouse, 2000; Uphouse *et al.*, 2003). That 5-HT<sub>1A</sub> receptors facilitate copulatory behavior in male rats, while inhibiting sexual behavior in female rats, seems, at first, to contradict this suggestion. However, rapid ejaculation in the presence of a potential threat would maximize the rat's probability both of escaping predation and of producing offspring. To delay ejaculation in the presence of a threatening environment reduces the rat's probability of survival. With this perspective, the occurrence of species differences in the response to a drug such as 8-OH-DPAT (which is facilitatory in male rats but inhibitory in male mice) begins to coalesce in that the drug primarily functions to inhibit sexual activity. Therefore, from this perspective, 5-HT<sub>1A</sub> receptor activation produces a comparable sexual consequence (e.g., acts as a brake on sexual activity) in males and females. Such a perspective is also consistent with evidence that 5-HT<sub>1A</sub> receptors antagonists, alone, do not seem to increase sexual behavior, but have the ability to attenuate inhibition induced by 5-HT releasing agents or by stressful events (Uphouse *et al.*, 2007).

Given the lack of a large amount of data for other receptor subtypes, it may be premature to attempt to identify additional unifying roles. However, data for 5-HT<sub>2</sub> receptors fit well within the above theme. 5-HT<sub>2</sub> receptors are implicated in the facilitation of female sexual behavior, as well as in male sexual motivation and erection. Of interest, then, is the reciprocal role played by 5-HT<sub>2C</sub>

receptors in sexual and eating behavior, increasing sexual behavior (Nedergaard *et al.*, 2004; Giuliano, 2007) but reducing food intake (Langhans, 2007; Somerville *et al.*, 2007). Moreover, 5-HT<sub>1A</sub> and 5-HT<sub>2</sub> receptors seem to function together to fine-tune the behavioral outcome (Berendsen and Broekkamp, 1990; Krebs-Thomson and Geyer, 1998; Mikkelsen *et al.*, 2004).

Thus, 5-HT's role in modulation of sexual behavior is likely to be far more complex than any identification of its facilitatory or inhibitory components. Instead, 5-HT's widespread distribution in the CNS and the periphery enables the neurotransmitter to facilitate selection of one set of behavioral outcomes at the expense of another. In many cases, this behavioral competition sacrifices sexual activity while facilitating behaviors that may be more conducive to individual survival.

# Serotonin in Mood and Emotion

Julie G. Hensler\*

*Department of Pharmacology, University of Texas Health Science Center-San Antonio, San Antonio, Texas*

**Abstract:** The topographical organization of serotonergic innervation of the forebrain, as well as the paracrine nature of serotonergic neurotransmission in limbic structures, support the contention that serotonin plays a neuromodulatory role in the brain. The lack of synaptic specializations at serotonergic terminals and varicosities in many brain regions suggests that serotonergic innervation may be particularly pliable. As conscious feeling or the cognitive aspect of emotion involves learning and memory, the serotonergic system may be particularly well suited for modulating mood. Pharmacological manipulations of serotonergic neurotransmission alter emotional processing, attentional bias, emotional memory, dysfunctional attitudes and decision-making. In healthy human subjects, increases in serotonergic neurotransmission result in enhanced attention and recognition of positive emotional material. Contrary to expectation, acute increases in serotonergic neurotransmission also increase attentional bias towards negative or fearful stimuli. In general, decreased serotonergic neurotransmission results in impaired attention and recognition of positive emotional material, and increases the attentional bias towards negative stimuli in healthy subjects. A polymorphism in the serotonin transporter gene also alters emotional processing. Understanding not only the neurobiology of emotional responses, but also serotonergic modulation of emotional states, will be important as we attempt to elucidate the etiology of emotional disorders. Future research with agents specific to various serotonin receptors may identify important therapeutic targets for the treatment of cognitive and affective disorders.

**Keywords:** limbic system, serotonin receptors, tryptophan depletion, selective serotonin reuptake inhibitors, serotonin transporter, MDMA, fenfluramine.

## Introduction

Webster's *New Collegiate Dictionary* defines mood as a conscious state of mind or predominant emotion. Emotion is defined as the affective aspect of consciousness. In addition to this conscious feeling or cognitive aspect of emotion, there is a visceral component, specifically the characteristic physical responses associated with emotional state. The present chapter focuses on the role of the neurotransmitter serotonin (5-hydroxytryptamine; 5-HT) in mood and emotion. A brief overview of the limbic system and innervation of these structures in brain, which are responsible for emotion, by serotonergic neurons is provided before discussing serotonergic modulation of emotion. In many instances, review articles are cited, in addition to original papers, in the hope that the interested reader will pursue these topics further. The role of serotonin, however, in psychopathologies or clinical disease states will not be specifically addressed in this chapter. The reader is referred

to Chapters 4.2, 4.9 and 4.10 for the role of serotonin in major depressive disorder, in anxiety and panic disorders, and in aggression and violent behavior, respectively.

## Neuroanatomy of emotion

The neural representation of feelings and emotion lies in the limbic system of the brain. The limbic system is composed of cortical as well as subcortical structures, which are intimately interconnected. The major structures of the limbic system include the prefrontal cortex, cingulate cortex, entorhinal cortex, hippocampus, nucleus accumbens (ventral striatum), ventral pallidum, amygdala, and anterior hypothalamus (Swanson and Petrovich, 1998; Iversen *et al.*, 2000; Heimer, 2003). Connections between these structures form complex circuits. For an excellent review of the organization of major neuronal circuits and neurochemical networks of the limbic system, the reader is referred to Morgane *et al.* (2005). As emphasized by Morgane *et al.* (2005), complex psychological states such as emotion and mood warrant consideration of the corre-

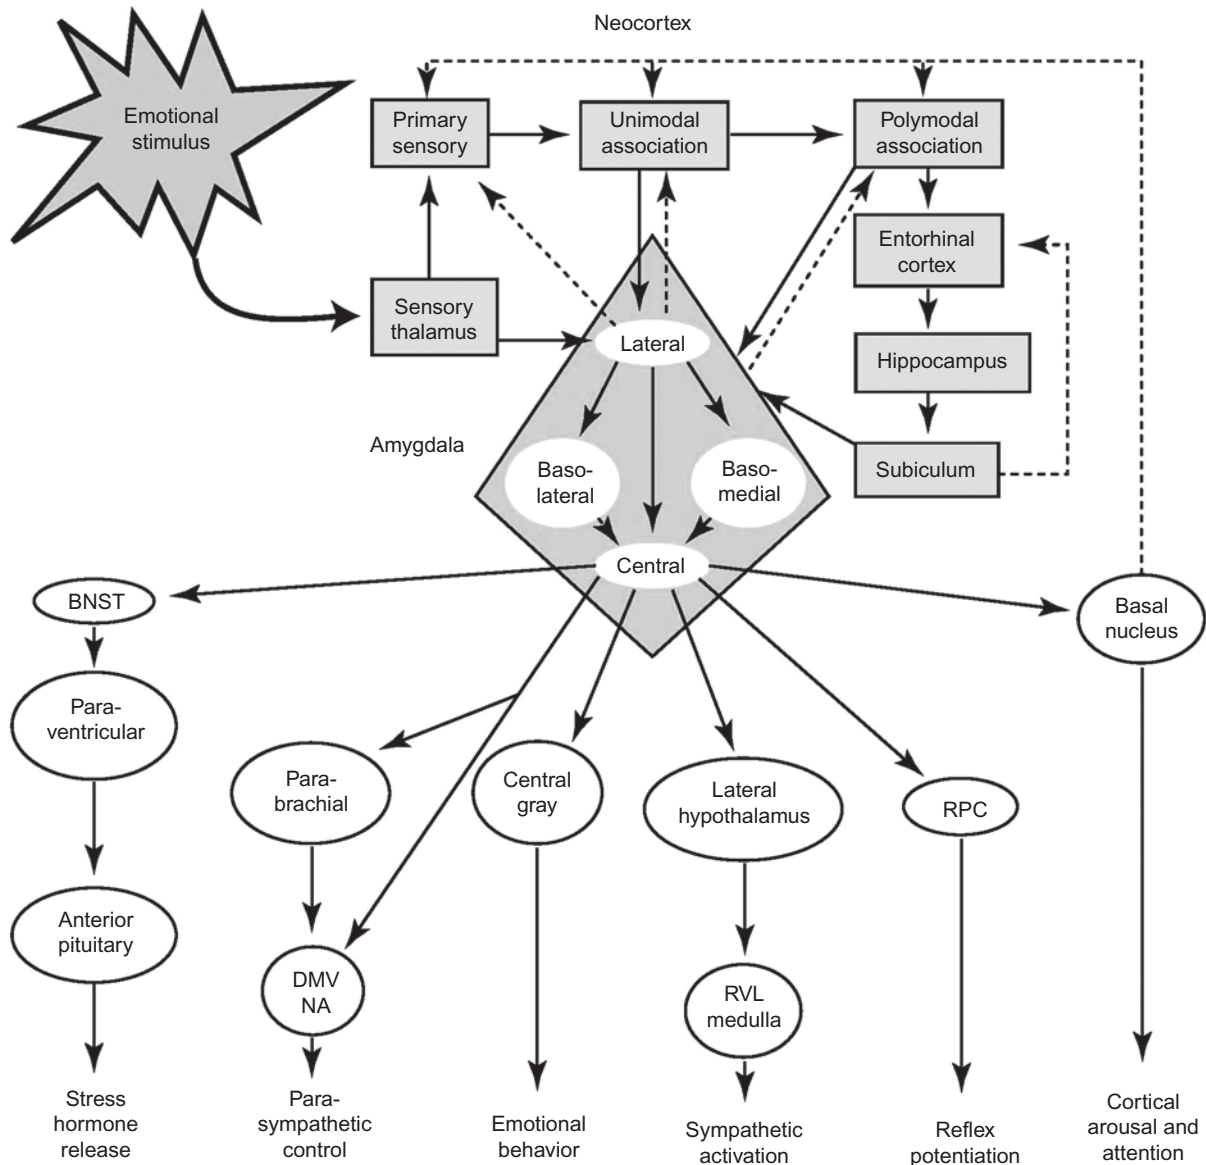

\*E-mail: hensler@uthscsa.edu

sponding anatomical components as a whole, in that these psychological processes are not performed by single structures but by complexes of interacting systems in the brain.

The unconscious, visceral responses associated with emotion are mediated by subcortical areas. These systemic autonomic, endocrine and skeletal motor responses involve connections between the nuclei of the amygdala, the hypothalamus and the brainstem (Figure 1). The lower brainstem and spinal cord receive extensive connections from the limbic forebrain and limbic midbrain, and constitute a major output for the limbic system (Holstege, 1992;

Holstege and Georgiadis, 2004). Cell body groups for various neurotransmitters are located in the midbrain – for example, serotonin (raphe nuclei), dopamine (substantia nigra and ventral tegmental area), acetylcholine (latero-dorsal and pedunculopontine tegmental nuclei), norepinephrine (locus coeruleus) and epinephrine (nucleus of the solitary tract). The limbic midbrain can be divided into ventral and medial components. The medial tegmentum consists of the raphe nuclei, the central gray and the dorsal and ventral tegmental nuclei of Gudden. The lateral tegmentum is comprised of the ventral tegmental area, the

**Figure 1** The amygdala serves as a hub, connecting the hypothalamus and brainstem, responsible for unconscious visceral responses associated with emotion, with cortical areas and hippocampus responsible for conscious feeling or cognitive aspects of emotion. BNST, bed nucleus of the stria terminalis; DMV, dorsal nucleus of the vagus; NA, nucleus ambiguus; RPC, nucleus reticularis pontis oralis; RVL, rostral ventral nucleus of the medulla. This figure was published in Eichenbaum, H.B., 'Learning and memory: brain systems', pp. 1299–1328, *Fundamental Neuroscience*, 2nd edition, edited by L.R. Squire *et al.* Copyright Elsevier (2003).

locus coeruleus, the substantia nigra, the nucleus ambiguus and the nucleus tractus solitarius. The hypothalamus is important in the regulation of homeostasis, and serves to integrate autonomic responses and endocrine function to maintain the constancy of the internal environment. The hypothalamus, which is intimately linked to the brainstem and limbic forebrain, coordinates the peripheral expression of emotion (Iversen *et al.*, 2000). For an excellent review and discussion of the limbic midbrain, and the involvement of the lower brainstem and spinal cord in unconscious visceral or somatic responses associated with emotion, the reader is referred to Morgane *et al.* (2005) and Morgane and Mokler (2006).

The amygdala is central to both cognitive and visceral aspects of emotion, in that it plays a critical role in coordinating the conscious experience of emotion and the peripheral expressions of emotion. The amygdala serves as a hub, connecting the hypothalamus and brainstem with cortical areas and hippocampus (Figure 1). Thus, the amygdala is not only essential for the expression of inherent or inborn emotional responses, but also plays a critical role in the acquisition and expression of learned emotional responses (see, for example, Armony and LeDoux, 1997; Hamann *et al.*, 1999; Baxter and Murray, 2002; Phelps and LeDoux, 2005). The reciprocal connections between the amygdala and the neocortex permit the incorporation of learning and experience into the cognitive aspects of emotion (Figure 1). For example, neuroimaging studies indicate that the amygdala and orbitofrontal cortex are common brain structures involved in the recognition and processing of facial expressions representing a variety of emotions (e.g., fear, disgust, sadness, happiness, and anger); both structures are activated by the perception of different emotional faces (Del-Ben *et al.*, 2008).

Conscious feeling or the cognitive aspect of emotion is believed to be mediated by the hippocampus and neocortex. Neuronal connections from hippocampus and neocortical areas to the amygdala make it possible for not just external stimuli but also memory and imagination to evoke emotional responses or feelings (Iversen *et al.*, 2000). The amygdala, in combination with the hippocampus and prefrontal cortex, plays an important role in the retrieval of memories for emotional events (Buchanan, 2007). As proposed by Armony and LeDoux (1997), the amygdala integrates various sensory and cognitive inputs from forebrain structures (i.e., the thalamus, hippocampus and neocortex). The thalamus provides information as to the basic nature or features of the stimulus, while cortical areas and the hippocampus provide additional 'higher-order' information about the complex nature of the stimulus. The hippocampus also plays a critical role in setting the emotional context (Williams *et al.*, 2005; Gentili *et al.*, 2008; Marschner *et al.*, 2008; Park *et al.*,

2008). The extinction of emotional responses is an active form of learning, and is mediated by a network of three structures: the amygdala, hippocampus and prefrontal cortex (see, for example, Phelps and LeDoux, 2005; Quirk and Mueller, 2008).

As discussed above, forebrain structures including orbitofrontal cortex, anterior cingulate cortex, insula and amygdala mediate higher-order emotional processing and learning. These involve the representation of stimulus values, the emotional enhancement of sensory processing, and predictions of values associated with actions in order to bias decision-making. Neuroimaging studies have provided substantial information about the neural basis of emotion, specifically the functional anatomy of emotion. The reader is referred to the following for recent reviews of the neuroanatomy of laughter (Meyer *et al.*, 2007), love (Zeki, 2007), regret (Coricelli *et al.*, 2007) and aversive emotional experiences (Phelps and LeDoux, 2005).

### Serotonergic innervation of the limbic system

Especially high levels of serotonin are found in limbic forebrain structures. Serotonin projections to these forebrain structures arise from serotonergic cell body groups in the midbrain. Dahlström and Fuxe (1964), using the Falck-Hillarp technique of histofluorescence, observed that the majority of serotonergic soma were found in cell body groups previously designated by Taber *et al.* (1960) as the raphe nuclei based on cytoarchitectural criteria – i.e., on cell body structural characteristics and organization. Dahlström and Fuxe described nine groups of serotonin-containing cell bodies, designated B1–B9, which correspond for the most part with the raphe nuclei (Descarries *et al.*, 1982; Kohler and Steinbusch, 1982; Molliver, 1987; Törk, 1990).

Although serotonin-containing neuronal cell bodies are restricted to discrete groups of cells or nuclei located along the midline of the brainstem, their axonal projections innervate nearly every area of the central nervous system. Serotonergic cell body groups B1–B4 are more caudally situated (mid-pons to caudal medulla), and give rise to serotonergic axons that project within the brainstem and to the spinal cord. Ascending serotonergic projections innervating the forebrain, including limbic areas, arise primarily from the dorsal raphe (B6 and B7), median raphe (B8) and B9 cell group (Parent *et al.*, 1981; Kohler and Steinbusch, 1982). These serotonergic neurons form a dense plexus of axonal processes. The serotonergic projections, arising primarily from the dorsal and median raphe nuclei, compose two distinct serotonergic systems that differ in their electrophysiological characteristics (Kirby *et al.*, 2003; Beck *et al.*,

2004), topographic organization and morphology, as well as sensitivity to neurotoxins and perhaps psychoactive or therapeutic agents (Molliver, 1987). These differences may be extremely important for understanding the role of these two serotonergic systems in normal brain function and in mental illness. For a more detailed description of serotonergic innervation of limbic structures, the reader is referred to Hensler (2006).

In many areas of the limbic system, serotonergic neurotransmission can best be described as paracrine or volume transmission, which requires that the neurotransmitter diffuses to remote receptor sites. Extensive ultrastructural studies by Descarries and colleagues (Descarries and Mechawar, 2000; see also Chapter 1.4 of this volume) have shown that in the cerebral cortex and hippocampus of the rat, the majority of serotonergic varicosities are not associated with synaptic specializations. These findings indicate that the serotonergic innervation of cortex and hippocampus is predominantly non-junctional; specifically, high densities of small vesicles exist in varicosities lacking synaptic specializations and located far from any recognizable postsynaptic density. Additional factors determining the type of neurotransmission (i.e., restricted to the synaptic cleft or 'hard-wired' versus diffuse volume transmission) include the location of receptors with respect to release sites, the amount of neurotransmitter released, the rate of diffusion away from the release site, and the removal or reuptake of the neurotransmitter by its transporter. The extrasynaptic location of serotonin receptors and the serotonin transporter is further evidence for paracrine serotonergic neurotransmission in many areas of brain (Hensler, 2006).

It has been proposed by Descarries that neuronal varicosities deprived of synaptic attachment might undergo translocation and reshaping along their parent fiber, and that in the absence of synaptic junctions, the released neurotransmitter might diffuse in the intercellular space to act on relatively distant cellular targets (Descarries *et al.*, 1975; Beaudet and Descarries, 1976). This raises intriguing possibilities for synaptic plasticity, and specifically for the pliant or tractable nature of the functional architecture of serotonergic neurons innervating structures of the limbic system. As conscious feeling or the cognitive aspect of emotion involves learning and memory, the serotonergic innervation of the forebrain may be particularly well suited for modulating mood.

### Serotonergic modulation of emotion

The topographical organization of serotonergic innervation of forebrain structures (Molliver, 1987) as well as the paracrine nature of serotonergic neurotransmission in limbic

structures support the contention that serotonin plays a neuromodulatory role in the brain.

Not surprisingly, then, serotonin neurotransmission is important in determining emotional information processing and mood. Pharmacological manipulations of the serotonergic systems in the brain affect attentional bias, recognition of facial emotion, emotional memory, dysfunctional attitudes and decision-making. Negative biases in information processing may play a role in the maintenance of major depressive disorder. For excellent recent reviews evaluating the literature pertaining to serotonin, emotional information processing, cognition and depression, the reader is referred to Merens *et al.* (2007) and Harmer (2008).

### Agents that increase serotonergic neurotransmission

Tryptophan is an essential amino acid found in dietary protein, and a precursor to serotonin in its synthesis. Supplementing the diet with tryptophan is believed to increase serotonin synthesis and therefore neurotransmission. In healthy volunteers, increased secretion of anterior pituitary hormones and a psychological state mimicking the effect of serotonergic antidepressants are taken as an indication that brain serotonergic function is increased (Cowen, 1993; Yatham and Steiner 1993; Attenburrow *et al.*, 2001; Harmer *et al.*, 2003a). Increased brain serotonergic function by acute dietary supplementation with tryptophan appears to have broad effects on cognitive performance in healthy subjects, and may impair affective working memory (Luciana *et al.*, 2001). As discussed below, increased serotonergic neurotransmission results in enhanced attention and recognition of positive emotional material. Contrary to expectation, acute increases in serotonergic neurotransmission also increase the attentional bias towards negative or fearful stimuli. In normal, healthy subjects, these cognitive changes, and changes in emotional processing, are not accompanied by changes in mood (Merens *et al.*, 2007; Del-Ben *et al.*, 2008; Harmer, 2008).

Identification or recognition of facial expressions representing basic emotions has been widely used to investigate the functional anatomy and neurochemistry of emotion. Acute tryptophan loading by administration of a single dose of nutritionally sourced tryptophan facilitates the perception of facial expressions of both happiness and fear in healthy female volunteers (Attenburrow *et al.*, 2003). This increased threat processing, as well as the bias in emotional processing towards positive emotional material, is also observed in healthy volunteers following a single dose of the selective serotonin reuptake inhibitor (SSRI) citalopram (Table 1). Acute administration of citalopram to healthy volunteers of both genders improves

performance in recognizing happy facial expressions (Harmer *et al.*, 2003a) and shifts attentional bias towards positive words (Browning *et al.*, 2007). Acute citalopram administration has also been shown to improve or facilitate the recognition of fearful facial expressions, and to enhance fear-potentiated startle to predictable and unpredictable shocks (Harmer *et al.*, 2003a; Browning *et al.*, 2007; Grillon *et al.*, 2007). Taken together, these studies

indicate that increases in serotonergic neurotransmission are not anxiogenic in the absence of threatening or fearful stimuli, but increase threat processing and exacerbate anxiety experienced in responses to threat. That acute increases in serotonergic neurotransmission increase recognition of and attention to both positive and negative emotional material suggests that serotonin may have a general effect on attention and perception.

**Table 1** Serotonergic modulation of emotion in healthy human subjects

<b>Agents that increase serotonergic neurotransmission</b>				
Acute tryptophan loading	Females	↑	Recognition of happy facial expressions	Attenburrow <i>et al.</i> , 2003
		↑	Recognition of fearful facial expressions	
Acute SSRI administration	Both genders	↑	Recognition of happy facial expressions	Harmer <i>et al.</i> , 2003b; Browning <i>et al.</i> , 2007
		↑	Recognition of fearful facial expressions	
		↑	Attentional bias toward positive words	Browning <i>et al.</i> , 2007
Repeated tryptophan administration	Females	↑	Fear potentiated startle responses	Grillon <i>et al.</i> , 2007
		↑	Recognition of happy facial expressions	Murphy <i>et al.</i> , 2006
	Males	↓	Recognition of disgusted facial expressions	
		↔	Recognition of happy facial expressions

	Males	↔	Recognition of emotional facial expressions	
4 days after MDMA	Both genders	↓	Recognition of fearful facial expressions	Hoshi <i>et al.</i> , 2004

It might be expected that increased threat processing in healthy volunteers, as a result of acute increases in central serotonergic neurotransmission, would be accompanied by increases in the activation of the amygdala to fearful faces. However, neuroimaging studies have shown that increases in serotonergic function following acute administration of an SSRI attenuate amygdala activation (Moret and Briley, 1996; Attenburrow *et al.*, 2001; David *et al.*, 2003; Felton *et al.*, 2003; McKie *et al.*, 2005). Following acute citalopram administration, activation of the right orbitofrontal cortex (BA47) and amygdala in response to aversive or fearful faces is decreased (Del-Ben *et al.*, 2005; Anderson *et al.*, 2007). These studies of Del-Ben *et al.* (2005) and Anderson *et al.* (2007) were, however, conducted only in male subjects, and there is considerable evidence for sexual dimorphism in emotional processing (Cahill, 2006).

A longer period of dietary supplementation with tryptophan (i.e., for 14 days) has been found to facilitate the recognition of happy expressions and decrease the recognition of disgusted faces in healthy women; the perception of fearful faces is not changed (Murphy *et al.*, 2006). Interestingly, this positive bias in the processing of emotional material as a result of longer periods of tryptophan supplementation is not observed in male volunteers (Murphy *et al.*, 2006). A similar bias of emotional processing away from negative and towards positive emotional material is observed following administration of the SSRI citalopram to healthy volunteers of both genders for 7 days. While acute administration of an SSRI increases the processing of both happiness and fear in healthy individuals, repeated administration of an SSRI to healthy subjects results in a decreased recognition of anger and fear (Harmer *et al.*, 2004, 2006a). Repeated citalopram administration to healthy volunteers also increased memory for positive material, and specifically increased recall of words associated with positive personality traits (Harmer *et al.*, 2004) (Table 1). Differences between the effect of acute and of chronic increases in serotonergic neurotransmission on emotional processing may be related to compensatory, neuroadaptive changes that occur with prolonged increases in serotonergic neurotransmission – e.g., the down-regulation or desensitization of specific serotonin receptors as a result of increased extracellular serotonin. That repeated dietary supplementation with tryptophan, or repeated administration of SSRIs, increases recognition of happy emotional faces and recall of positive material, and decreases perception of fearful faces, suggests a divergence of emotional processing for positive and negatively valenced material.

As has been demonstrated for acute administration of SSRIs, neuroimaging studies indicate that administration of citalopram for 7 days to healthy volunteers of both genders decreases activation of the amygdala in response to

fearful faces versus happy faces (Harmer *et al.*, 2006a). Administration of the SSRI escitalopram (the active, S-isomer of citalopram) to healthy volunteers for 21 days also attenuates activation of the amygdala in response to negatively, but not positively, valenced emotional faces (Arce *et al.*, 2008).

MDMA (3,4-methylenedioxymethamphetamine) inhibits serotonin reuptake and stimulates the release of serotonin stored in presynaptic vesicles. MDMA also inhibits the catabolic enzyme monoamine oxidase (MAO), reducing the metabolism of serotonin within the nerve terminal and therefore contributing to the increased release of serotonin by MDMA (Green *et al.*, 2003). Immediately following an acute dose, MDMA elicits an intense positive emotional state accompanied by feelings of empathy, sociability and closeness; these are believed to be a result of increased serotonergic neurotransmission (Mørland, 2000; Baylen and Rosenberg, 2006), although MDMA also increases dopaminergic and noradrenergic neurotransmission through similar mechanisms (Green *et al.*, 2003). MDMA also facilitates the recognition of fearful faces after acute administration (Hoshi *et al.*, 2004). The increased accuracy of fear recognition may be due to increased serotonin release as a result of MDMA administration (Green *et al.*, 1995), consistent with enhanced threat processing observed following increased serotonergic neurotransmission as a result of acute administration of the SSRI citalopram or acute dietary supplementation with tryptophan (Table 1).

Fenfluramine is a substrate for the serotonin transporter, and is a potent releaser of serotonin from nerve terminals. It is believed that fenfluramine releases serotonin from neurons via a non-exocytotic, carrier-mediated exchange mechanism involving the serotonin transporter. The metabolite norfenfluramine is a potent serotonin 5-HT<sub>2B</sub> and 5-HT<sub>2C</sub> receptor agonist (Rothman and Baumann, 2002). Increasing serotonin function by administration of d-fenfluramine to healthy subjects results in a reduction in dysfunctional attitudes, specifically negatively biased views of oneself, the world and the future that are exaggerated in depression (Meyer *et al.*, 2003; Table 1).

### Agents that decrease serotonergic neurotransmission

Intake of a mixture of essential amino acids free of tryptophan, the precursor of 5-HT synthesis, results in a reduction of brain serotonergic function. Acute tryptophan depletion is therefore a useful tool to investigate the effects of lowered serotonin function in humans. Acute tryptophan depletion results in a temporary depressive relapse in recovered depressed patients taking serotonergic antidepressants (Delgado *et al.*, 1990; Van der

Does, 2001). However, only small effects (i.e., lowered or decreased mood) are found in healthy subjects, and especially in those subjects with a family history of affective disorders (Ellenbogen *et al.*, 1999; Klaassen *et al.*, 2002). In general, as discussed below, decreased serotonergic neurotransmission results in impaired attention and recognition of positive emotional material, and increases the attentional bias towards negative stimuli in healthy subjects. The shift in attentional bias toward negative emotional material may be related, however, to the type of test or task performed.

Acute tryptophan depletion impairs recall of neutral and positive, but not negative, words in healthy volunteers (Klaassen *et al.*, 2002). Reaction time of healthy control subjects to emotionally charged stimuli compared with neutral stimuli is increased in the emotional Stroop task, an indication that healthy volunteers are more easily distracted by negative stimuli after acute tryptophan depletion (Hayward *et al.*, 2005). In healthy female volunteers, acute tryptophan depletion slows responses to happy, but not sad, target words in the affective go/no-go task (Murphy *et al.*, 2002); this, however, has not been a consistent observation (Rubinsztein *et al.*, 2001; Table 1).

In contrast to the observed shift in attentional bias to negative material in verbal tasks, acute tryptophan depletion has been found to impair the recognition of fearful facial expressions by healthy female volunteers (Harmer *et al.*, 2003b), and enhance the recognition of happy facial expressions in healthy volunteers of both genders (Hayward *et al.*, 2005). These results are in agreement with the observations that increased serotonin function, by acute administration of the SSRI citalopram or by acute dietary supplementation with tryptophan, results in increased threat processing and shifts attentional bias towards negative or fearful stimuli (Attenburrow *et al.*, 2003; Harmer *et al.*, 2003a; Browning *et al.*, 2007) (Table 1).

Neuroimaging studies indicate that the decreases in serotonin synthesis and function in brain as a result of tryptophan depletion in healthy men and women enhance amygdala activation in response to fearful faces in contrast to happy faces (Cools *et al.*, 2005; van der Veen *et al.*, 2007). This is in contrast to what has been shown following acute or repeated SSRI administration, as discussed above.

In addition to inducing an acute and rapid release of serotonin, MDMA inhibits the activity of tryptophan hydroxylase, the rate-limiting enzyme required for serotonin synthesis (Green *et al.*, 2003). Decreased serotonin synthesis, as a result of the inhibition of tryptophan hydroxylase, causes serotonin depletion. Serotonergic neurotransmission is therefore reduced during the days following MDMA administration. Four days after MDMA

administration, the perception of fearful faces is impaired (Hoshi *et al.*, 2004). This decrease in the accuracy of fear recognition is believed to be due to the subsequent depletion of serotonin (Green *et al.*, 1995). Decreased serotonergic neurotransmission may also be responsible for undesirable emotional and cognitive effects experienced more intensely following MDMA use. These include negative mood, impaired concentration, lack of energy, irritability, agitation, depression and anxiety (Mørland, 2000; Green *et al.*, 2003; Baylen and Rosenberg, 2006). MDMA exposure may also result in long-term neurotoxic damage to serotonergic neurons. Administration of MDMA to rodents and non-human primates results in a long-term reduction in serotonin levels in several brain regions; biochemical and histological evidence indicates that this reflects degeneration of serotonergic terminals (Green *et al.*, 1995). Limited, indirect clinical evidence indicates that similar changes may occur in human brain with MDMA exposure, although whether long-term neurotoxic effects seen in animals occurs in humans has yet to be unequivocally demonstrated (Green *et al.*, 2003; Cowen, 2007).

### Serotonin transporter gene polymorphism and emotional processing

The serotonin transporter is responsible for terminating the action of serotonin in the extracellular space through the energy dependent reuptake of serotonin into the presynaptic terminal. Thus, the serotonin transporter plays a key role in regulating serotonergic neurotransmission. The serotonin transporter gene (5-HTTLPR) has two frequent alleles, designated long (*l*) and short (*s*). The *s*-allele results in decreased serotonin transporter function and expression *in vitro* (Heils *et al.*, 1995, 1996; Lesch *et al.*, 1996). A functional, single nucleotide variant has been recently detected within the *l*-allele, designated *l<sub>A</sub>* and *l<sub>G</sub>*. *l<sub>A</sub>* is associated with increased expression of the serotonin transporter *in vitro*, whereas *l<sub>G</sub>* is similar to *s* in being associated with low expression (Nakamura *et al.*, 2000; Hu *et al.*, 2006). Imaging studies using the new and highly selective ligand [<sup>11</sup>C]DASB have extended these *in vitro* studies, reporting that these alleles are indeed associated with differences in serotonin transporter expression *in vivo* (Praschak-Rieder *et al.*, 2007; Reimold *et al.*, 2007).

Emotional appraisal, or how emotions are interpreted and reflected upon, is one of the most important aspects of emotional regulation. A recent study has compared emotional appraisal profiles of negative (fear and sadness) and positive (joy) emotions as a function of serotonin transporter gene alleles. Healthy volunteers that carry the *s*-allele of the serotonin transporter gene score higher

than non-carriers for unpleasantness and goal-hindrance, and scored lower for coping ability in the case of fear and sadness (Szily *et al.*, 2008) (Table 2). These findings suggest that the *s*-allele, which conveys decreased function and expression of the serotonin transporter, is associated with a vulnerable cognitive style related to the appraisal of negative emotions (Szily *et al.*, 2008). Indeed, the *s*-allele has been shown to be associated with major depressive disorder in those who have experienced traumatic or stressful life events (see, for example, Caspi *et al.*, 2003; Kendler *et al.*, 2005; Jacobs *et al.*, 2006) (Table 2).

The effect of acute tryptophan depletion on the processing of emotional facial expressions has also been shown to vary as a function of genotype at the 5-HTTLPR. Tryptophan depletion significantly impairs the recognition of fearful facial expressions in carriers of the *s*-allele (Marsh *et al.*, 2006). This impairment is specific to fear expressions. However, in healthy volunteers homozygous for the *l*-allele, acute tryptophan depletion did not alter the recognition of fearful faces (Marsh *et al.*, 2006). The findings of this study suggest that individuals homozygous for the *l*-allele are less sensitive to the effects of tryptophan depletion on emotional processing (Table 2).

Low expression and/or function of the serotonin transporter associated with the *s*-allele might be expected to result in increased serotonin in the extracellular space, and enhanced emotional processing of positively valenced material as a result of increased serotonergic neurotransmission. However, genetic determinants of serotonin transporter function most likely result in physiological and neuroadaptive changes during development, and may not necessarily result in increases in serotonergic neurotransmission in the long term. For example, serotonin transporter knockout mice exhibit a variety of neurologi-

cal and physiological abnormalities, and exhibit enhanced fear, and anxiety-like and depression-like behaviors (for review, see Murphy and Lesch, 2008).

Carriers of the *s*-allele of the serotonin transporter exhibit increased activation of the amygdala in response to fearful stimuli compared with individuals homozygous for the *l*-allele (Hariri *et al.*, 2002) (Table 2). These results indicate genotype-related differences in excitability of the amygdala to emotional stimuli, which may contribute to the increased fear and anxiety typically associated with the *s*-allele (Murphy and Lesch, 2008). Morphometrical analyses indicate genotype-related differences in anatomy as well. Healthy individuals who are carriers of the *s*-allele have reduced gray matter volume in limbic regions believed to be critical for the processing of negative emotion, specifically perigenual cingulate and amygdala (Pezawas *et al.*, 2005). Neuroimaging techniques show tight functional coupling of these brain regions during perceptual processing of fearful stimuli. The functional connectivity between these brain regions is critical for emotion regulation and for the extinction of negative affect and fear (see, for example, Pezawas *et al.*, 2005; Phelps and LeDoux, 2005; Quirk and Mueller, 2008). Most interestingly, *s*-allele carriers showed a relative uncoupling of this circuit, which inversely predicted almost 30 percent of variation in temperamental anxiety (Pezawas *et al.*, 2005). These functional and neuroanatomical studies provide evidence of a systems-level mechanism underlying normal emotional reactivity and genetic susceptibility for depression.

Agents acting directly on specific subtypes of serotonin receptor

A recent review by Engin and Treit (2008) provides an extensive overview of the effects of intracerebral infusion of a variety of agents on animals' unconditioned fear reactions. Of interest are 5-HT<sub>1A</sub> and 5-HT<sub>3</sub> receptors. 5-HT<sub>1A</sub> receptors are found in high density in the dorsal and median raphe, where they function as somatodendritic autoreceptors. These receptors, when activated by serotonin or agonist, decrease serotonergic neuronal firing. 5-HT<sub>1A</sub> receptors are also located postsynaptically to serotonergic neurons, and are present in high density in cortical and limbic structures (see Hensler, 2003, and references therein). In general, 5-HT<sub>1A</sub> receptor agonists produced anxiolytic-like behavioral effects in animal models when infused into the dorsal or median raphe nuclei. However, inconsistent effects have been reported when 5-HT<sub>1A</sub> receptor agonists are injected into the amygdala, septum and hippocampus (Engin and Treit, 2008). Most of the experimental findings to date are in agreement with

Table 2 Serotonin transporter gene polymorphism and emotional processing

<i>s</i> -allele carriers ( <i>s/s</i> , <i>s/l</i> )

<i>l</i> -allele homozygotes ( <i>l/l</i> )		
↔	Recognition of emotional facial expressions with tryptophan depletion	Marsh <i>et al.</i> , 2006

the hypothesis that increases and decreases in serotonergic output from the raphe translate into anxiogenic and anxiolytic effects, respectively. However, overall the data are not entirely consistent with this view. Inconsistencies in the literature may be due in part to the variety of behavioral tests used and the complexity of inhibitory feedback mechanisms, which include circuits involving frontal cortex and amygdala (Ceci *et al.*, 1994; Bosker *et al.*, 1997; Hajos *et al.*, 1999; Celada *et al.*, 2001).

The 5-HT<sub>3</sub> receptor is the only serotonin receptor that is a member of the ligand-gated ion channel superfamily of receptors. Specifically, this receptor is a cation channel that is gated by serotonin. In brain, 5-HT<sub>3</sub> receptors are found in cortical and limbic structures. This localization is consistent with behavioral studies in animals that suggest that 5-HT<sub>3</sub> receptor antagonists may have potential anxiolytic, antidepressant and cognitive effects (Barnes and Sharp, 1999; Costall and Naylor, 2004). 5-HT<sub>3</sub> receptor antagonists produce anxiolytic-like effects in the amygdala (Engin and Treit, 2008). The anxiety-related effects of ligands of other serotonin-receptor subtypes have been inconsistent after infusion into the amygdala. Other receptors of interest for future studies include 5-HT<sub>2</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptors in cortical areas.

Surprisingly little work has been done to investigate the effects of agents that act on specific subtypes of serotonin receptor on emotional processing in humans. Harmer *et al.* (2006b) have examined the effects of the 5-HT<sub>3</sub> receptor antagonist ondansetron on facial emotion recognition, emotional categorization and memory, and emotion-potentiated startle, in healthy volunteers. Although ondansetron did not affect subjective measures of mood, anxiety or wellbeing, ondansetron did reduce the emotion-potentiated startle, especially in response to negative pictures. Interestingly, facial expression recognition and emotional memory were not significantly altered, in contrast to the effects of acute SSRI administration on facial emotion recognition (Harmer *et al.*, 2006b). These findings are consistent with those of animal studies, and suggest a role for 5HT<sub>3</sub> receptors in some elements of fear processing.

## Conclusion

The effects of manipulations in serotonergic neurotransmission on cognition and emotion are complex. This is perhaps not unexpected, based on the dense plexus of innervation of forebrain limbic structures by serotonergic neurons arising from the dorsal and median raphe. The very nature of serotonergic neurotransmission in many brain regions is consistent with a neuromodulatory role of this neurotransmitter. Understanding not only the

neurobiology of emotional responses, but also the serotonergic modulation of emotional states, will be important as we attempt to elucidate the etiology of emotional disorders. By examining how emotional responses can be manipulated, we may be able to change maladaptive emotional reactions. Future research with agents specific to various serotonin receptors may identify important therapeutic targets for the treatment of cognitive and affective disorders.

# Serotonin and the Neurobiology of Anxious States

Christopher A. Lowry<sup>\*,1,2</sup> and Matthew W. Hale<sup>1</sup>

<sup>1</sup>*University of Colorado at Boulder, Department of Integrative Physiology, Boulder, Colorado*

<sup>2</sup>*University of Bristol, Henry Wellcome Laboratories for Integrative Neuroscience and Endocrinology, Bristol, UK*

**Abstract:** Anxious states are emotional states associated with an increase in avoidance behavior, particularly in situations where a conflict between approach and avoidance occurs, as when both potential rewarding outcomes and potential aversive outcomes exist. An important component of anxious states is that they are trans-situational, transferring from one situation to another. Serotonergic systems play an important role in modulating anxious states. Serotonergic signaling can either facilitate or attenuate anxious states, depending on the site of action and the specific serotonin receptor subtype involved. In this chapter, we present an operational definition of anxious states, describe a number of stimuli that can induce anxious states with distinct time-courses, and consider the evidence that serotonergic systems play a role in modulation of these anxious states. We focus on a subpopulation of serotonergic neurons that projects to forebrain limbic structures implicated in the regulation of anxious states, including the ventral hippocampus/subiculum and the basolateral amygdaloid complex. We then compare and contrast this serotonergic system with another serotonergic system implicated in the inhibition of panic-like responses, a principal component of a subset of anxiety disorders in humans.

**Keywords:** 5-hydroxytryptamine, anxiety, basolateral amygdala, bed nucleus of the stria terminalis, circuit, hippocampus, raphe, serotonin.

**Abbreviations:** 5-HTT, 5-hydroxytryptamine transporter, serotonin transporter; 5-HTTLPR, 5-HTT-linked polymorphic region; BB<sub>1</sub>, bombesin-like peptide type I receptor; BB<sub>2</sub>, bombesin-like peptide type II receptor; CCK, cholecystokinin; CRF, corticotropin-releasing factor; CRF<sub>1</sub>, corticotropin-releasing factor type I receptor; CRF<sub>2</sub>, corticotropin-releasing factor type II receptor; dHPC, dorsal hippocampus; DMCM, methyl 6,7-dimethoxy-4-ethyl-beta-carboline-3-carboxylate; DPAG, dorsal periaqueductal gray; DRN, dorsal raphe nucleus, dorsal part; DRV/VLPAG, dorsal raphe nucleus, ventrolateral part/ventrolateral part of the periaqueductal gray; FG-7142, N-methyl-β-carboline-3-carboxamide; fMRI, functional magnetic resonance imaging; GABA, γ-aminobutyric acid; MNR, median raphe nucleus; RVLM, rostral ventrolateral medulla; SERT, 5-hydroxytryptamine transporter, serotonin transporter; SSRI, selective serotonin reuptake inhibitor; TPH2, tryptophan hydroxylase 2; vHPC, ventral hippocampus.

## Introduction

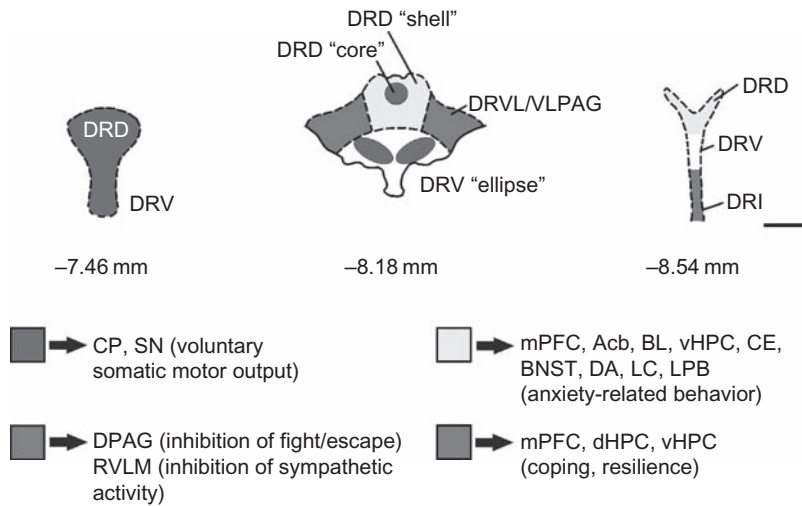

### *Aims and scope of the chapter*

Anxious states and anxiety-related behaviors appear to be regulated by a distributed and interconnected network of neural circuits in the brain. Serotonin is an important modulator of these anxiety-related circuits, but the mechanisms through which serotonin modulates these circuits and the associated physiological and behavioral arousal are not well understood. The current chapter has three aims: (1) to present an operational definition of anxious states and

anxiety-related behavior; (2) to briefly define neural systems involved in modulating anxiety-related behaviors; and (3) to consider how serotonergic systems specifically modulate these anxiety-related circuits.

Serotonergic systems are topographically organized. This means that serotonergic neurons located in different parts of the brainstem raphe complex give rise to projections to specific and different neural targets (Figure 1). In order to understand the role of serotonergic systems in the regulation of anxious states and anxiety-related behavior, it is important to characterize the anatomical and functional properties of those serotonergic neurons that project to neuronal structures that regulate anxiety. It is not possible within the constraints of this chapter to consider the effects of serotonergic

**Figure 1** Diagrammatic illustration of the topographical distribution of serotonergic neurons projecting to functionally related forebrain and hindbrain targets in the rat brain. Serotonergic neurons projecting to the caudate putamen and substantia nigra (blue) are located predominantly in the rostral part of the DR and are concentrated within clusters in the DRD 'core' and DRV 'ellipse' regions of the mid-rostrocaudal parts of the DR. Serotonergic neurons projecting to brain structures implicated in the regulation of anxious states and anxiety-related behaviors (yellow) are concentrated in the mid-rostrocaudal DRD 'shell' region and caudal DR. Populations of serotonergic neurons in the DRVL/VLPAG region (red) project to the DPAG and RVLM and have been implicated in the inhibition of panic-like responses. Serotonergic neurons in the DRI (green) have projections to the prefrontal cortex, hippocampus, and mid-line thalamus, are thought to be activated by peripheral immune activation, and may play an important role in coping and resilience. Abbreviations: Acb, nucleus accumbens; BL, basolateral amygdala; BNST, bed nucleus of the stria terminalis; CE, central nucleus of the amygdala; CP, caudate putamen; DA, dorsal hypothalamic area; dHPC, dorsal hippocampus; DRD, dorsal raphe nucleus, dorsal part; DRI, dorsal raphe nucleus, interfascicular part; DRV, dorsal raphe nucleus, ventral part; DRVL/VLPAG, dorsal raphe nucleus, ventrolateral part/ventrolateral periaqueductal gray; DPAG, dorsal periaqueductal gray; LC, locus coeruleus; LPB, lateral parabrachial nucleus; mPFC, medial prefrontal cortex; RVLM, rostral ventrolateral medulla; SN, substantia nigra; vHPC, ventral hippocampus. Scale bar, 500  $\mu$ m. Reproduced from *Stress: The Biology Of Stress*, 12 January 2005, Christopher A. Lowry, Philip L. Johnson, Anders Hay-Schmidt *et al.* 'Modulation of anxiety circuits by serotonergic systems' 8:4, pp. 233–246, reprinted by permission of Taylor & Francis Ltd, <http://www.tandf.co.uk/journals>. systems on all components of a distributed neuronal circuit regulating anxiety; instead we will focus on the ventral hippocampus/subiculum and the basolateral nucleus of the amygdala, two important components of the neural circuits modulating anxiety-related behavior in situations that involve conflict between approach and avoidance. We will also briefly discuss the dorsal periaqueductal gray (DPAG) and rostral ventrolateral medulla (RVLM), two important components of the neural circuits determining vulnerability to panic-like responses, a significant component of some anxiety disorders, such as panic disorder and post-traumatic stress disorder (PTSD) in humans.

### **Operational definition of anxious states and anxiety-related behavior**

In this chapter, we will consider two different symptoms associated with anxiety disorders in humans that can be modeled in animal studies. The first is an *emotional state* of anxiety that involves a conflict when both

potential rewarding and aversive outcomes are present; this emotional state leads to increased avoidance of potentially aversive outcomes. The second is a *vulnerability* to panic-like responses following exposure to normally innocuous stimuli, a component of some anxiety disorders including panic disorder and PTSD (American Psychiatric Association, 2000). The former, also referred to as conflict anxiety, is a complex emotional state associated with increased vigilance and arousal, and a sustained increase in avoidance behavior in environmental situations characterized by a level of uncertainty or unpredictability, including situations where a conflict between approach and avoidance behaviors exists (Figure 2). An important element of the emotional state of anxiety is that it is trans-situational. In other words, the anxiety state transfers to different environments or situations (Figure 2). Panic-like responses include increases in heart rate and blood pressure, and escape-like behaviors (Graeff *et al.*, 1996; Shekhar *et al.*, 2003). The neural circuits regulating anxious states and vulnerability to panic-like

**Figure 2** Diagrammatic illustration of a model of conflict anxiety. In a highly predictable environment the individual is faced with a straightforward behavioral strategy, approach-type behaviors in the case of a rewarding outcome and avoidance-type behaviors in the case of an aversive outcome. However, in a complex unpredictable environment the individual may perceive simultaneously the potential for both rewarding and aversive outcomes of specific behavioral strategies. This conflict, between approaching a potentially rewarding stimulus and avoiding a potentially aversive stimulus, is central to many anxiety-states. Anxiolytic drugs (benzodiazepines) or stimuli (safety signals) can shift the balance towards approach-type behaviors, while anxiogenic drugs (FG-7142, caffeine) or stimuli (bright light in rodents) can shift the balance towards avoidance-type behaviors. An important component of anxious states is that the associated increases in physiological and behavioral arousal are not tied to a specific context, but are trans-situational. Serotonin can have anxiolytic or anxiogenic effects depending on the site of action and the 5-HT receptor subtype involved.

responses are different, and therefore we would expect that the serotonergic systems modulating them would be different.

### *Models of anxious states with distinct temporal profiles*

An emotional state of anxiety can be induced by a number of drugs or experiential factors. Anxious states can be transient, lasting a few minutes, a few hours, a few days, or even a lifetime, in which case the individual is said to have anxiety traits. Anxiety traits can be dependent on genetic influences or developmental factors during early life. Below, we consider different pharmacological, experiential or genetic influences that can increase anxious states or lead to development of persistent anxiety traits.

The most extensively studied model of anxious states is treatment with anxiogenic drugs, including  $\beta$ -carbolines, inverse partial agonists and agonists that act at the benzodiazepine allosteric site of the GABA<sub>A</sub> receptor, such as N-methyl- $\beta$ -carboline-3-carboxamide (FG-7142) (Evans and Lowry, 2007) and methyl 6,7-dimethoxy-4-ethyl-beta-carboline-3-carboxylate (DMCM) (Cole *et al.*, 1995), and

benzodiazepine antagonists such as flumazenil (File and Pellow, 1984). These drugs can act very quickly, within 5 minutes, to induce an anxiety state that, depending on the dose used, can last 30–90 minutes (Evans and Lowry, 2007). Other classes of anxiogenic drugs include adenosine receptor antagonists such as caffeine, 5-HT<sub>2A/2C</sub> receptor agonists such as m-chlorophenyl piperazine (mCPP), and  $\alpha_2$ -adreno-receptor antagonists such as yohimbine (for references, see Singewald and Sharp, 2000; see Singewald *et al.*, 2003). These drugs appear to activate a common, distributed neural system in the brain, including the basolateral nucleus of the amygdala, bed nucleus of the stria terminalis, and brainstem monoaminergic systems including noradrenergic and serotonergic systems (Singewald and Sharp, 2000; Singewald *et al.*, 2003; Abrams *et al.*, 2005; Evans and Lowry, 2007). These common effects are observed despite the fact that the drugs have such diverse pharmacological specificity, suggesting that there are many nodes through which this anxiety circuitry can be activated. Importantly for this chapter, these drugs activate a subpopulation of serotonergic neurons within the dorsal raphe nucleus, discussed further below.

A number of endogenous anxiogenic neuropeptides and neurotransmitters are implicated in activation of anxiety circuits and induction of anxious states, including corticotropin-releasing factor (CRF) acting at CRF type I (CRF<sub>1</sub>) receptors (Dunn and Berridge, 1987; Heinrichs *et al.*, 1997), cholecystokinin acting at CCK<sub>A</sub> and CCK<sub>B</sub> receptors (Harro, 2006), bombesin-like peptides acting at BB<sub>1</sub>/BB<sub>2</sub> receptors (Merali *et al.*, 2006), noradrenaline acting at  $\alpha_1$  and  $\beta$  adrenoceptors (Morilak *et al.*, 2005), and serotonin acting at 5-HT<sub>2C</sub> receptors (Anderson *et al.*, 2002; Campbell and Merchant, 2003). The anxiogenic effects of activation of these neuropeptide or neurotransmitter receptors are evident quickly, and, depending on the dose, can last up to several hours.

Environmental stimuli can also increase anxiety state. These stimuli tend to be diffuse, species-specific aversive cues, such as bright light in rodents (for review, see Walker *et al.*, 2003). Rodents avoid bright light and open spaces – conditions that increase the likelihood of aversive events, including predation. Effectively, any stimulus that increases the perceived threat or increases the perceived potential for aversive outcomes can increase anxiety state. Bright light induced anxiety in rodents has a rapid onset, evident within 5–20 minutes, and persists for approximately 20 minutes after the light is turned off (see, for example, Walker *et al.*, 2003; Bouwknecht *et al.*, 2007). Other aversive experiences can also increase anxiety state. An extensively studied model in rodents is the increase in anxiety state induced by exposure to immobilization stress. The anxiety state induced by immobilization stress has a rapid onset, occurring within 15 minutes, but is transient (Cecchi *et al.*, 2002a, 2002b). Other aversive

experiences also induce a trans-situational anxiety state; these include shock (see below), predator odor (Adamec *et al.*, 2006), swim stress (Heinrichs *et al.*, 1994), restraint (Heinrichs *et al.*, 1994; Martijena *et al.*, 1997; Mendonca and Guimaraes, 1998), social defeat (Heinrichs *et al.*, 1992, 1994; Ruis *et al.*, 1999) and predator exposure (Adamec and Shallow, 1993; Adamec *et al.*, 2004; for review, see Korte and De Boer, 2003; Armario *et al.*, 2008).

If the aversive experience is intense and unmanageable, such as repeated, uncontrollable shock, it can induce a prolonged increase in anxiety state that lasts up to 24–72 hours (Gewirtz *et al.*, 1998; for review, see Walker *et al.*, 2003; Maier and Watkins, 2005). The extended time-course of increased anxiety state following intense, uncontrollable stress suggests that unique mechanisms are involved, relative to anxiety states with shorter time-courses. In studies of social avoidance, shock-induced increases in anxiety state can last up to 5–10 days (Leveleki *et al.*, 2006). Social defeat by a conspecific may be an ethologically relevant model of intense, uncontrollable stress that also leads to a prolonged increase in anxiety state, an emotional state that can last at least 2 weeks (Ruis *et al.*, 1999; Nakayasu and Ishii, 2008). Interestingly, the prolonged anxiety state following social defeat is abrogated if the animal is put in social housing conditions (Ruis *et al.*, 1999; Nakayasu and Ishii, 2008). Likewise, the prolonged anxiety state following repeated shock is abrogated if the animal has control over termination of the shock (Maier and Watkins, 2005). The effect of stressor controllability to prevent the development of subsequent anxious states is dependent on activation of the medial prefrontal cortex and the consequent inhibition of serotonergic neurons in the caudal dorsal raphe nucleus (Maier and Watkins, 2005).

Many of the pharmacological and experiential anxiogenic stimuli described above share in common that they activate a subset of serotonergic neurons within the mid-rostrorocaudal and caudal dorsal raphe nucleus, a region that gives rise to the majority of serotonergic projections to forebrain structures controlling anxious states and anxiety-related behavior. This will be discussed further below. Perhaps more importantly, in many of the cases described above, the development of anxiety states and expression of anxiety-related behavior appears to be dependent on activation of serotonergic systems (Maier and Watkins, 2005; Merali *et al.*, 2006; Meloni *et al.*, 2007; Sziray *et al.*, 2007; Cooper *et al.*, 2008; Harada *et al.*, 2008; Strong *et al.*, 2008).

### *Models of anxious traits*

Anxiety traits are stable individual differences, resulting in an increased tendency to respond with state anxiety to

environmental situations. Genetic composition plays an important role in determining anxiety traits. In addition, a lifelong increase in anxiety trait can result from a number of adverse experiences, either during prenatal or neonatal development, or in adolescence.

### *Genetic models*

Genetic influences play an important role in determining anxiety traits, including genes that control serotonergic neurotransmission. A key step in regulating 5-HT neurotransmission at the synapse is its rapid reuptake into the presynaptic terminal by the serotonin transporter (SERT; 5-HTT). Thus, blocking SERT with selective serotonin reuptake inhibitors (SSRIs) has become the most effective strategy to treat mood and anxiety disorders over the past three decades. This large-scale use of SSRIs in treating mood and anxiety disorders and the genetic heterogeneity of responses to SSRIs has also facilitated the demonstration that the SERT expression in the brain is a major determinant of not only the response to SSRIs, but also coping with stress and the risk of development of mood and anxiety disorders (Lesch *et al.*, 1996; Ogilvie *et al.*, 1996; Rotondo *et al.*, 2002; Van den Hove *et al.*, 2006). A common polymorphism consisting of short (*s*) versus long (*l*) forms of the promoter region of the SERT gene *slc6A4* (5-HTTLPR) has been associated with variability in rates of SERT transcription and serotonin reuptake (Lesch *et al.*, 1996). A number of recent reports have provided data supporting the hypothesis that genetic polymorphisms in 5-HTTLPR may determine the efficacy of (Smeraldi *et al.*, 1998; Pollock *et al.*, 2000; Rausch *et al.*, 2003) as well as the side effects (Perlis *et al.*, 2003) seen with antidepressants that are serotonin reuptake inhibitors – e.g., the SSRIs. Individuals with *s/s* (population frequency, 20 percent) and *s/l* genotypes (population frequency, 40 percent) have reduced SERT sites compared to individuals who are homozygous for the long allele (*l/l*) (population frequency, 40 percent) (Lotrich *et al.*, 2001). Individuals with *s/s* and *s/l* have been shown to have decreased antidepressant response and increased side effects compared to individuals with the *l/l* phenotype (Smeraldi *et al.*, 1998; Pollock *et al.*, 2000).

More importantly, recent studies in healthy subjects have reported that the 5-HTTLPR polymorphism regulating SERT expression also determines amygdala activation in response to negative stimuli as measured with functional magnetic resonance imaging (fMRI) (Hariri *et al.*, 2002, 2005). In these studies, subjects with one or more *s* allele were shown to have increased amygdala activation in response to a facial emotion recognition task. Genetic variation in SERT expression is an important

factor in regulating neuroticism, anxiety response and amygdala activation in healthy volunteers (Heinz *et al.*, 2005; Brocke *et al.*, 2006; Canli *et al.*, 2006; Rhodes *et al.*, 2007; Smolka *et al.*, 2007), as well as development of anxiety disorders and depression (Munafo *et al.*, 2008). Lower SERT expression is a strong vulnerability factor for increased risk of anxiety disorders (Furmark *et al.*, 2004; Hariri and Holmes, 2006; Maron and Shlik, 2006; Xu *et al.*, 2006), perhaps due to developmental effects or to compensatory responses following chronic elevation of synaptic serotonin concentrations. Low availability of SERT measured *in vivo* is correlated with anxiety in patients with major depression (Reimold *et al.*, 2008). Therefore, low SERT expression appears to greatly facilitate amygdala excitation and vulnerability to anxiety and mood disorders by an as yet unknown mechanism.

Animal models with reduced SERT expression, similar to humans, likewise appear to have a vulnerability to development of anxious states. For example, SERT knockout mice, but not their heterozygous or wild-type counterparts, respond with a persistent increase in anxious state following exposure to predator odor (Adamec *et al.*, 2006, 2008). Mice and rats with inactivation of SERT expression demonstrate increases in anxiety traits (Kalueff *et al.*, 2007; Olivier *et al.*, 2008). Conversely, mice with overexpression of SERT have a low anxiety phenotype (Jennings *et al.*, 2006).

Evidence suggests that polymorphisms in other genes that are important determinants of serotonergic neurotransmission also affect anxiety traits. A variety of evidence supports a role for abnormal 5-HT<sub>1A</sub> receptor function in panic disorder and social anxiety disorder. These receptors are found both postsynaptically and presynaptically, where they mediate somatodendritic negative feedback inhibition of serotonergic neuronal firing. Patients with panic disorder show subsensitivity of these receptors in laboratory challenge tests (Lesch *et al.*, 1992). Neumeister *et al.* (2004) reported reduced amounts of 5-HT<sub>1A</sub> receptor binding using positron emission tomography (PET) in unmedicated patients with panic disorder compared to healthy controls, especially in the amygdala, cingulate cortex and midbrain raphe complex. Another study recently confirmed this by demonstrating reduced 5-HT<sub>1A</sub> receptor binding in the amygdala and midbrain raphe complex of subjects with panic disorder using [<sup>11</sup>C]WAY-100635, a more selective PET ligand for 5-HT<sub>1A</sub> receptors (Nash *et al.*, 2008). Another PET study using [<sup>11</sup>C]WAY-100635 as the ligand found reduced 5-HT<sub>1A</sub> receptor binding in subjects with social anxiety disorder (Lanzenberger *et al.*, 2007). The G allele of the C(-1019)G variant of the 5-HT<sub>1A</sub> receptor has been associated with depression, panic disorder, neuroticism, and reduced response to antidepressant drug treatment (Drago *et al.*, 2008; Le *et al.*, 2008).

Mice with genetic inactivation of the 5-HT<sub>1A</sub> receptor display increased anxiety traits (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998; Gross *et al.*, 2002). This phenotype can be reversed by selective expression of 5-HT<sub>1A</sub> receptors within dentate granule cells in the hippocampus, including the ventral hippocampus (Tsetsenis *et al.*, 2007), suggesting an important role for 5-HT<sub>1A</sub> receptors in hippocampal circuitry in the regulation of anxious states (see below).

Although less is known about associations between 5-HT<sub>2A</sub> receptor function and anxiety disorders, at least one study has reported association of polymorphism in the 5-HT<sub>2A</sub> receptor gene and panic disorder (Inada *et al.*, 2003), while recent independent studies have found that polymorphisms in the 5-HT<sub>2A</sub> receptor are associated with symptom severity in panic disorder (Unschuld *et al.*, 2007; Yoon *et al.*, 2008). Thus, genetic studies support a role for both 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors in the pathophysiology and symptom severity of anxiety disorders.

Mice with genetic inactivation of 5-HT<sub>2A</sub> receptors have decreased anxiety traits as measured in conflict anxiety tests (Weisstaub *et al.*, 2006). Selective restoration of 5-HT<sub>2A</sub> receptors, principally in layer V of the cortex, reversed the anxiety phenotype (Weisstaub *et al.*, 2006), suggesting that cortical 5-HT<sub>2A</sub> receptors normally play a role in development of anxiety traits.

Individuals with a single nucleotide polymorphism C178T in the regulatory region of the serotonin receptor type 3 gene (*htr3A*) show altered amygdala activation during a face recognition task (Iidaka *et al.*, 2005). Individuals with the C/C phenotype had greater activity in the amygdala and dorsal and medial prefrontal cortices than those with the C/T phenotype. Mice with genetic deletion of the 5-HT<sub>3</sub> receptor show reduced anxiety traits (Kelley *et al.*, 2003; Bhatnagar *et al.*, 2004), consistent with the hypothesis that the 5-HT<sub>3</sub> receptor may play a role in development of anxiety traits. Altogether, these genetic studies in humans and rodents suggest that 5-HT<sub>1A</sub> receptors (particularly hippocampal 5-HT<sub>1A</sub> receptors) decrease anxiety traits, while 5-HT<sub>2A</sub> receptors (particularly cortical 5-HT<sub>2A</sub> receptors) and 5-HT<sub>3</sub> receptors play a role in facilitation of anxiety traits. Clarification of the role of these receptors in the modulation of anxious states and the development of anxiety traits, as well as the involvement of other serotonin receptor subtypes in development of anxiety traits, will require further study.

#### *Adverse early life experience models*

Maternal stress during pregnancy can result in long-term increases in anxiety traits (for review, see Weinstock, 2008). A variety of psychological and physical stressors

during gestation, including restraint (Van den Hove *et al.*, 2005), footshock (Estanislau and Morato, 2005), exposure to the synthetic glucocorticoid dexamethasone (Nagano *et al.*, 2008) and exposure to a predator (Patin *et al.*, 2005), can result in increased anxiety traits in offspring. The long-term behavioral consequences of prenatal stress appear to be sex-specific (Weinstock, 2007). Restraint stress during the final 10 days of gestation results in increased anxiety-like behavior in the elevated plus maze test in male offspring, but a reduction of anxiety-like behavior in female offspring (Zuena *et al.*, 2008). As well as the long-term behavioral consequences, maternal stress also induces neurobiological changes in the offspring (Weinstock, 2008). Exposure to prenatal stress is associated with changes in cell morphology (Kraszpulski *et al.*, 2006), higher levels of CRF (Cratty *et al.*, 1995), and greater numbers of CRF receptors (Ward *et al.*, 2000) in the basolateral amygdala. Importantly in the context of this chapter, prenatal stress results in a decrease in 5-HT<sub>1A</sub> receptor binding in male, but not female, pups in the ventral, but not dorsal, hippocampus (Van den Hove *et al.*, 2006). These changes in the neurobiology of the basolateral amygdala and ventral hippocampus may have important consequences in the development of anxiety traits in adult rats.

Adverse early life experience during the neonatal period can result in increased anxiety traits that persist throughout the lifetime of the organism. Exposure of rats to prolonged periods of neonatal maternal separation has been suggested as an animal model of vulnerability to development of anxiety states and a depression-like syndrome (Willner, 1990; Hall, 1998; Plotsky *et al.*, 1998; Ladd *et al.*, 2000). Although the mechanisms involved are not clear, this vulnerability is associated with increased CRF receptor expression in the dorsal raphe nucleus (Ladd *et al.*, 1996), and changes in serotonergic systems within the brain, including altered stress-induced serotonergic neurotransmission during adulthood (Gartside *et al.*, 2003; Daniels *et al.*, 2004; van Riel *et al.*, 2004). In contrast, exposure of rats to short periods of neonatal maternal separation has been suggested as an animal model of resilience to stress and stress-related pathology, effects that are dependent on epigenetic programming and altered limbic serotonergic function (Smythe *et al.*, 1994; Meaney and Szyf, 2005).

Social isolation during a critical phase of development in adolescence results in persistent, stable increases in anxiety traits in adult rats (for review, see Fone and Porkess, 2008). Social isolation during adolescence increases anxiety-like behavior in the open-field (Hall, 1998), elevated plus maze (Wright *et al.*, 1991) and social interaction tests (Lukkes *et al.*, 2008a). The increase in anxiety traits in social isolates is associated with an up-regulation of CRF<sub>2</sub> receptors in the dorsal raphe nucleus, and facilitation of CRF-induced serotonin release in the

nucleus accumbens (Lukkes *et al.*, 2008b). Thus, adverse experience during prenatal, neonatal and adolescent periods can lead to development of anxiety traits in adulthood, possibly via alterations in serotonergic systems signaling to forebrain structures controlling anxious states and anxiety-related behavior.

### *Priming models*

Repeated subthreshold disinhibition or activation of key nodes of the anxiety circuitry (a process referred to as priming) can result in a persistent, seemingly permanent increase in anxiety state, and thus would be considered an anxiety trait. Priming of the basolateral amygdala results in increases in anxious states, as measured in a number of tests including the social interaction test and elevated plus maze test, but also results in vulnerability to panic-like responses to normally innocuous agents, such as sodium lactate (Sanders *et al.*, 1995; Sajdyk and Shekhar, 2000; Shekhar *et al.*, 1999, 2003, 2005). On the other hand, priming of the bed nucleus of the stria terminalis results in stable increases in anxious states as measured in the social interaction test but not the elevated plus maze test (Lee *et al.*, 2008). Similarly, rats subjected to priming of the bed nucleus of the stria terminalis do not display vulnerability to panic-like responses to sodium lactate (Lee *et al.*, 2008). Therefore, it has been suggested that priming of the basolateral amygdala may model anxiety disorders that include vulnerability to panic attacks, including panic disorder and PTSD, while priming of the bed nucleus of the stria terminalis may model social anxiety disorder (Lee *et al.*, 2008). Persistent disinhibition of key nodes of the anxiety circuitry, such as the bed nucleus of the stria terminalis (Sajdyk *et al.*, 2008) and dorsomedial hypothalamus (Shekhar *et al.*, 1996), can also result in a stable increase in anxious state and (in the case of the dorsomedial hypothalamus) vulnerability to panic-like responses to sodium lactate.

### *Interactions among genetic influences, adverse early life experience, and adverse experience during adulthood*

Interactions among the risk factors described above, such as genetic influences, adverse early life experience and stressful life experience during adulthood, are likely to play an important role in the development of anxiety traits in rodents and of anxiety and affective disorders in humans (see, for example, Caspi *et al.*, 2003).

### *Models of panic-like states*

As mentioned briefly above, animal models of a stable vulnerability to panic-like responses have been developed. For example, priming of the basolateral amygdala (Sajdyk

*et al.*, 1999; Sajdyk and Shekhar, 2000) or chronic disinhibition of the dorsomedial hypothalamus (Shekhar *et al.*, 1996) results in a persistent vulnerability to panic-like responses (tachycardia, hypertension) in response to i.v. infusions of sodium lactate.

### **Neural circuits modulating anxiety-related behavior and anxious states**

Attempts have been made to understand the neural systems involved in the modulation of the conflict between approach and avoidance that is inherent in many forms of anxious states (Gray, 1982; Gray and McNaughton, 1987, 2000; Millan, 2003). Intuitively, it seems that neural systems mediating approach and avoidance behaviors must be involved, but that higher-order processes are likely to be involved in predicting outcomes of specific behavioral responses and resolving conflicts between two opposing behavioral strategies. For example, Gray has suggested that the septo-hippocampal system plays a critical role in the neurobiology of anxious states, and in particular that it plays a critical role in predicting the outcome of specific behavioral responses – an idea elaborated in what is called the ‘comparator model of hippocampal function’ (Gray, 1982; Gray and McNaughton, 2000; Vinogradova, 2001). In the context of conflict anxiety the hippocampus acts as a comparator (Gray, 1982), comparing expected outcomes versus actual outcomes. According to this model, the hippocampus and the subiculum sample multimodal sensory information via connections with the entorhinal cortex (Witter *et al.*, 1988; Van Groen and Wyss, 1990; Tamamaki and Nojyo, 1995; Vinogradova, 2001) in order to detect mismatch between expected and actual outcomes. In the case of a mismatch between the expected and actual outcomes (unpredictability), as might occur during exposure to a novel environment, the CA1 region of the ventral hippocampus and subiculum send input to the basolateral amygdala, which is a critical structure in the regulation of anxiety-related behavior following unpredictable stimuli (Herry *et al.*, 2007). The basolateral amygdala attaches emotional salience to the novel stimulus, and regulates the autonomic (via connections with the central nucleus of the amygdala) and behavioral (via connections with the bed nucleus of the stria terminalis) responses to the anxiety-related stimulus. These ideas are consistent with recent findings that hippocampal ‘place cells’ encode not only instantaneous place, but also information about past and future events (Ferbinteanu and Shapiro, 2003; Jeffery, 2004). For example, some hippocampal place cells are modulated (either switched ‘on’ or ‘off’) depending on whether the rat is going to turn right or left in a maze to

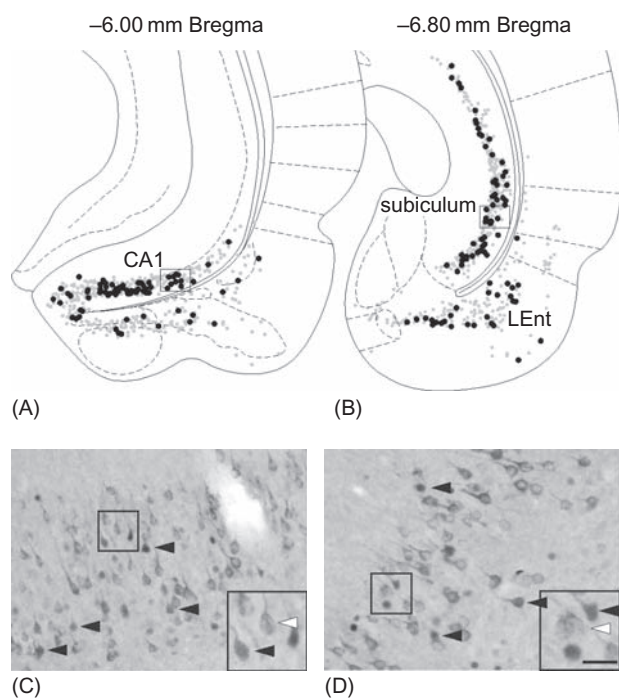

obtain a reward. This function of the hippocampus may be particularly relevant to risk assessment behavior, where predictions about the potential outcomes (rewarding/aversive) of different behavioral strategies (approach/avoidance) are required. If the outcome does not match the predicted outcome, the basolateral amygdala may be involved in assigning emotional salience to both potential rewarding and potential aversive outcomes. In support of a functional association between the hippocampus and the basolateral amygdala in the regulation of anxious states and anxiety-related behavior, we have recently reported that exposure to a mild anxiogenic stimulus (an open field arena in low-light conditions) activates basolateral amygdala-projecting neurons in the CA1 region of the ventral hippocampus, the entorhinal cortex and the subiculum, and that this activation is inversely correlated with habituation to the open field during the 15-minute test (Hale *et al.*, 2008a; Figure 3). That is, rats that did not habituate to the open field had a high level of activation of this anxiety circuit projecting to the basolateral amygdala.

### ***The basolateral amygdala as a nodal structure in anxiety-related circuits***

The basolateral amygdala is activated during anxious states, as determined using induction of immediate-early gene expression (Singewald *et al.*, 2003; Hale *et al.*, 2006). Consistent with a key role of the basolateral amygdala in the development of anxious states, inhibition of the basolateral amygdala following blockade of N-methyl-D-aspartate (NMDA) and non-NMDA receptors, or administration of the benzodiazepine receptor agonist midazolam, decreases anxiety-related behaviors (File and Gonzalez, 1996), while pharmacological activation of the basolateral amygdala with the GABA<sub>A</sub> receptor antagonist bicuculline methiodide, or the anxiety-related neuropeptides CRF or urocortin 1, increases anxiety-related behaviors (Sajdyk and Shekhar, 1997; Sajdyk *et al.*, 1999; Spiga *et al.*, 2006). As mentioned above, priming of the basolateral amygdala results in a persistent increase in anxious state. Imaging studies in humans, although they don’t have the resolution to specifically identify the basolateral amygdala, have consistently shown that the amygdala is activated during anxious states, including following challenge with anxiogenic drugs such as the 5-HT<sub>2A/2C</sub> receptor agonist mCPP (Anderson *et al.*, 2002).

### ***The ventral hippocampus/subiculum as a nodal structure in anxiety-related circuits***

The hippocampus is an important component of the distributed neuronal network regulating anxious states.

**Figure 3** Neural circuits underlying conflict anxiety. Retrograde tracing combined with detection of immediate-early gene induction reveals that basolateral amygdala-projecting neurons in the CA1 region of the ventral hippocampus, subiculum and entorhinal cortex are activated following exposure to a mild anxiogenic stimulus (exposure to an open-field under unfamiliar, low-light conditions). (A, B) Diagrammatic illustrations of basolateral amygdala-projecting neurons in (A) the ventral hippocampus at  $-6.00$  mm Bregma and (B) the subiculum and entorhinal cortex at  $-6.80$  mm Bregma. Basolateral amygdala-projecting neurons in the dorsal raphe nucleus were also activated (not shown), suggesting that a dorsal raphe nucleus–basolateral amygdala circuit modulates this anxiety network during anxious states. Rats received unilateral injection of the retrograde tracer Cholera Toxin B-subunit (CTb) into the basolateral amygdala. Seven days later rats were exposed to an open-field arena in unfamiliar, low-light conditions. Brains were then processed for immunohistochemical detection of c-Fos, as a marker of neuronal activation (c-Fos-ir), and for CTb, as a marker of basolateral amygdala-projecting neurons (CTb-ir). Black circles illustrate c-Fos-ir/CTb-ir neurons and the gray circles illustrate c-Fos-immunonegative/CTb-ir neurons. Black boxes in (A) and (B) are shown as photomicrographs in (C) and (D) respectively. (C) Photomicrograph illustrating c-Fos-ir nuclei and CTb-ir neurons in the CA1. (D) Photomicrograph illustrating c-Fos-ir nuclei and CTb-ir neurons in the subiculum and lateral entorhinal cortex (LEnt). Black arrowheads indicate examples of c-Fos-ir/CTb-ir neurons and white arrowheads indicate examples of c-Fos-immunonegative/CTb-ir neurons. Black boxes in C and D are shown at higher magnification in insets in the lower right-hand corner of each image. Abbreviations: CA1, CA1 region of the ventral hippocampus; LEnt, lateral entorhinal cortex. Scale bars,  $500\mu\text{m}$  (A, B),  $50\mu\text{m}$  (C, D),  $25\mu\text{m}$  (insets).

The hippocampus is not a homogeneous structure, however, and convergent lines of evidence suggest that there is a functional dissociation across its dorsal–ventral axis (Bannerman *et al.*, 2004). Neurons in the ventral

hippocampus that project to the basolateral amygdala are activated even following mild-anxiety challenges such as exposure to a novel open field under low-light conditions (Hale *et al.*, 2008a). Lesions to the ventral (vHPC), but not dorsal hippocampus (dHPC), reduce anxiety-related behavior in the social interaction test (McHugh *et al.*, 2004), the elevated plus maze (Kjelstrup *et al.*, 2002) and the novelty induced suppression of feeding test (McHugh *et al.*, 2004). Temporary inactivation of the vHPC with sodium channel blockers tetrodotoxin or lidocaine, or the NMDA-receptor antagonist ( $\pm$ )-2-amino5-phosphopentanoic acid (AP-5), decreases anxiety-related behavior in the elevated plus maze, while inactivation of the dHPC is without effect (Degroot and Treit, 2004; Bertoglio *et al.*, 2006; Nascimento Hackl and Carobrez, 2007). A proportion of neurons within the dorsal raphe nucleus that project to the basolateral amygdala also give rise to collateral (branched) projections to the vHPC (Imai *et al.*, 1986), suggesting that a subset of serotonergic neurons has coordinate control over these two components of anxiety circuitry.

### Neural circuits modulating vulnerability to panic-like responses
